## ASSESSMENT AND TREATMENT

Adherence to Treatment Regimens  
 AIDS and HIV: Adherence to Medications in Persons With HIV Infection  
 Alcohol Abuse and Dependence: Treatment  
 Anger: Measurement  
 Anxiety: Its Meaning and Measurement  
 Applied Behavior Analysis  
 Arthritis: Behavioral Treatment  
 Asthma: Behavioral Treatment  
 Biofeedback  
 Blood Pressure and Hypertension: Measurement  
 Blood Pressure and Hypertension: Physical Activity  
 Bulimia Nervosa: Treatment  
 Cancer: Psychosocial Treatment  
 Cancer Screening  
 Cardiac Rehabilitation  
 Cardiovascular Psychophysiology: Measures  
 Cardiovascular Reactivity  
 Chronic Disease Management  
 Chronic Obstructive Pulmonary Disease: Psychosocial Aspects and Behavioral Treatments  
 Chronic Pain Management  
 Complementary and Alternative Medicine  
 Depression: Measurement  
 Depression: Treatment  
 Diabetes: Behavioral Treatment  
 Doctor-Patient Communication  
 Drug Abuse: Behavioral Treatment  
 Eating Disorders

Ecological Momentary Assessment  
 Evidence-Based Behavioral Medicine  
 Expressive Writing and Health  
 Fibromyalgia Syndrome: Cognitive-Behavioral Treatment  
 Genetic Testing: Ethical, Legal, and Social Aspects  
 Headaches: Psychological Management  
 Health Care Costs and Behavior  
 Health Care Service Utilization: Determinants  
 Health Communication  
 Hostility: Measurement  
 Irritable Bowel Syndrome: Psychological Treatment  
 Minnesota Multiphasic Personality Inventory (MMPI/MMPI-2)  
 Motivational Interviewing  
 National Cholesterol Education Program (NCEP)  
 Obesity in Children: Physical Activity and Nutritional Approaches  
 Obesity: Prevention and Treatment  
 Optimism and Pessimism: Measurement  
 Physical Activity Interventions  
 Psychophysiology: Theory and Methods  
 Quality of Life: Measurement  
 Raynaud's Disease: Behavioral Treatment  
 Sleep Disorders: Behavioral Treatment  
 Smoking and Nicotine Dependence: Interventions

Smoking Prevention and Tobacco Control Among Youth  
 Support Groups and Health  
 Tailored Communications

## BASIC PROCESSES, THEORY, AND METHODOLOGY

Adoption of Health Behavior  
 Alcohol Abuse and Dependence  
 Allostatis, Allostatic Load, and Stress  
 Anger: Measurement  
 Anxiety: Its Meaning and Measurement  
 Behavioral Genetics and Health  
 Behavioral Risk Factor Surveillance System  
 Blood Pressure and Hypertension: Measurement  
 Cardiovascular Psychophysiology: Measures  
 Caregiving and Stress  
 Community-Based Participatory Research  
 Confounding  
 Cost-Effectiveness  
 Crowding and Health  
 Cultural Factors and Health  
 Depression: Measurement  
 Diffusion of Innovation  
 Discrimination and Health  
 Doctor-Patient Communication  
 Ecological Models: Application to Physical Activity  
 Ecological Momentary Assessment  
 Ecosocial Theory

Effect Modification  
 Effort-Reward Imbalance  
 Endogenous Opioids, Stress,  
 and Health  
 Erectile Dysfunction  
 Fibromyalgia Syndrome:  
 Biobehavioral Aspects  
 Fundamental Social Causes of  
 Disease and Mortality  
 Gastric Ulcers and Stress  
 Gate Control Theory of Pain  
 General Adaptation Syndrome  
 Genetic Testing: Ethical, Legal,  
 and Social Aspects  
 Health Belief Model  
 Health Communication  
 Hostility: Measurement  
 Immune Responses to Stress  
 Income Inequality and Health  
 Key Informants  
 Metabolic Syndrome and  
 Stress  
 Multilevel Methods, Theory, and  
 Analysis  
 Optimism and Pessimism:  
 Measurement  
 Participatory Research  
 Peptic Ulcers and Stress  
 Psychoneuroimmunology  
 Psychophysiology: Theory and  
 Methods  
 Quality of Life: Measurement  
 Repressive Coping and Health  
 Self-Efficacy  
 Smoking and Nicotine  
 Dependence  
 Social Capital and Health  
 Social Marketing  
 Social or Status Incongruence  
 Stress, Appraisal, and Coping  
 Stress: Biological Aspects  
 Stress-Buffering Hypothesis  
 Successful Aging  
 Television Viewing and  
 Health  
 Theory of Planned Behavior  
 Theory of Reasoned Action  
 Theory of Triadic Influence  
 Transtheoretical Model of  
 Behavior Change

Vital Exhaustion  
 Wound Healing and Stress  
**BIOPSYCHOSOCIAL  
 INTERACTIONS**  
 AIDS and HIV: Stress  
 Alcohol Abuse and Dependence  
 Allostatis, Allostatic Load, and  
 Stress  
 Anger and Heart Disease  
 Anger and Hypertension  
 Anger: Measurement  
 Anxiety, Heart Disease, and  
 Mortality  
 Asthma and Stress  
 Autoimmune Disorders:  
 Psychosocial Aspects  
 Behavioral Genetics and  
 Health  
 Blood Pressure, Hypertension,  
 and Stress  
 Cardiovascular Psychophysiology:  
 Measures  
 Cardiovascular Reactivity  
 Caregiving and Stress  
 Cerebrovascular Disease:  
 Psychosocial Aspects  
 Chronic Fatigue Syndrome:  
 Psychosocial Aspects  
 Chronic Illness: Psychological  
 Aspects  
 Chronic Obstructive Pulmonary  
 Disease: Psychosocial Aspects  
 and Behavioral Treatments  
 Community-Based Participatory  
 Research  
 Comorbid Mental and Other  
 Physical Disorders  
 Control and Health  
 Depression: Mortality and Other  
 Adverse Outcomes  
 Diabetes: Psychosocial Aspects  
 Drug Craving  
 Emotions: Negative Emotions and  
 Health  
 Emotions: Positive Emotions and  
 Health  
 Endogenous Opioids, Stress, and  
 Health  
 Erectile Dysfunction

Explanatory Style and Physical  
 Health  
 Fibromyalgia Syndrome:  
 Biobehavioral Aspects  
 Gastric Ulcers and Stress  
 General Adaptation Syndrome  
 Heart Disease: Anger, Depression,  
 and Anxiety

# Introduction

## RATIONALE

The field of health and behavior addresses the interaction of behavioral, psychological, emotional, social, cultural, and biological factors with physical health outcomes, such as heart disease, cancer, arthritis, diabetes, and chronic pain. The core philosophy of the field of health and behavior is threefold: (1) Behavioral, psychological, emotional, social, cultural, and biological factors are inextricably linked; (2) these factors together affect health; and (3) these factors can be used as avenues for prevention, treatment, and rehabilitation. Research and clinical practice in health and behavior are inherently multidisciplinary—that is, many disciplines contribute and no one discipline owns the field. Disciplines involved in health and behavior include psychology, epidemiology and public health, sociology, nursing, medicine, and anthropology, to name a few.

The field of health and behavior research is vast and ranges from the scientific examination of basic behavioral and social processes to the evaluation of preventive and treatment approaches to policy analysis. It addresses such varied topics as pain management, cardiac rehabilitation, social aspects of genetic testing, anxiety and heart disease, prevention of HIV/AIDS, stress effects on the immune system, approaches to smoking cessation, chronic disease management, community interventions, and socioeconomic status and health.

Health and behavior research has grown dramatically and has had increased visibility since the early 1980s. This growth is evidenced by a significant increase in the number of published scientific articles and books on the topic; the increase in funding for health and behavior research at federal and private funding agencies; and the appearance of health and behavior topics such as diet, exercise, smoking, and stress in popular publications and in electronic media. The growth, status, and potential of the field of health

and behavior were recently affirmed by two landmark reports from the National Academies: the Institute of Medicine's *Health and Behavior: The Interplay of Biological, Behavioral, and Societal Influences* (2001, Washington, DC: National Academy Press) and the National Research Council's *New Horizons in Health: An Integrative Approach* (2001, Washington, DC: National Academy Press). The 1995 opening of the Office of Behavioral and Social Sciences Research (OBSSR) at NIH is another example of the growth of the field. The OBSSR works across all of the institutes and centers of NIH to advance health and behavior research and other relevant areas.

Despite the tremendous growth and visibility of research on health and behavior, there existed no single reference source that captured the diversity and the multidisciplinary and transdisciplinary nature of the field and that was concise and accessible to lay audiences. The *Encyclopedia of Health and Behavior* was designed to be that reference source. The encyclopedia was designed to provide an introduction to the many topics in health and behavior for diverse audiences including undergraduate and graduate students in the behavioral and social sciences, medical students and those in the biomedical sciences, lay audiences (e.g., journalists, librarians, general public) seeking a nontechnical resource on health and behavior, and health scientists and practitioners who desire a quick reference source and introduction to areas outside their expertise.

## ORGANIZATION AND THEMES

The *Encyclopedia of Health and Behavior* is organized in an A–Z (alphabetical) format rather than by specific themes. In developing the topics that were to be included, however, the editors did rely on several different content areas or themes. These themes included, but were not limited to, the following:

- *Theories and methods in health and behavior* (e.g., the theory of planned behavior, health belief model, and multilevel methods theory)
- *Biopsychosocial interactions and basic behavioral and social processes* (e.g., behavioral genetics, psychoneuroimmunology, and cardiovascular reactivity)
- *Epidemiology of risk and protective factors* (e.g., the relationship to health and illness of factors such as diet, bereavement, acculturation, social capital, anxiety, social support, and stress)
- *Health promotion and disease prevention* (e.g., HIV/AIDS prevention, health promotion in schools, tailored communications, and church-based interventions)
- *Treatment and rehabilitation* (e.g., behavioral and psychological treatment of diabetes, drug abuse, fibromyalgia, asthma, headaches, and pain; doctor-patient communication; motivational interviewing; and adherence)
- *Policy and organizational issues* (e.g., health care costs and behavior, and health and behavior organizations)

Within the encyclopedia, considerable use is made of cross-referencing. That is, at the end of many of the entries there is information to guide readers to other related entries or further reading.

## EDITORIAL PROCESS

The editorial process began with the appointment of the six associate editors and six senior advisers. The members of these groups were selected because of their scientific leadership and vast knowledge of research on health and behavior. They also represented a number of disciplines, given the multidisciplinary nature of health and behavior. These individuals reviewed and revised a preliminary list of topics and potential headwords constructed by the editor in chief. The associate editors then selected Advisory Committee members, who also reviewed the preliminary topics and headword list and added potential titles. Many of these Advisory Committee members ultimately became contributing authors.

From the revised headword list, the associate editors and the editor in chief then identified and invited contributing authors to write the entries. Once entries were written and submitted, the associate editors were responsible for reviewing and editing these manuscripts.

Many of the associate editors also contributed entries themselves. Following the associate editors' review of the entries, they were submitted to the editor in chief for a final review.

## ACKNOWLEDGMENTS

I am fortunate to have had the opportunity to serve as editor in chief for this very special and first-of-its-kind publication. I wish to thank the Harvard School of Public Health for providing the ideal intellectual setting in which to work on this project. The volume would not have been possible without the encouragement, support, and guidance of Jim Brace-Thompson of Sage Publications, who believed from the start that an encyclopedia of this type would make a substantial contribution to the public health literature. Jim's expertise in behavioral and social science publishing, and especially in putting together encyclopedias, made my job so much easier. I am indebted to my managing editors, initially Mary Riso, and later Karen Ehrmann. They handled nearly all of the day-to-day work on the volume, including helping to identify and contact possible contributing authors, answering their many questions, prompting them to complete their entries, and ensuring that I stayed on task.

The associate editors cannot be thanked enough. These are all extraordinarily busy scientists and administrators who volunteered to spend a great deal of time on this project, when they could have been writing grant proposals or research papers. These people, because of their talent and expertise, are asked to do many things and are pulled in many directions. For them to take this on is a testament to their dedication to advancing the field of health and behavior. I will be forever grateful to them, as well as to our senior advisers and Advisory Committee members.

Most important, I wish to thank the contributing authors. Like the associate editors, the contributing authors are scholars with much on their professional plates, and they could have easily turned down the offer to write an entry due to time constraints. But they too recognized that the production of the first encyclopedia devoted exclusively to health and behavior research, which would cut across all of the disciplines that compose it, was an important development for our field. This encyclopedia is the result of their incredible efforts and the research conducted by scores of scientists.

—Norman B. Anderson

# About the Editor

**Norman B. Anderson, PhD**, is Chief Executive Officer and Executive Vice President of the American Psychological Association (APA). Trained as a scientist and a practitioner, Dr. Anderson has dedicated much of his professional life to studying the relationships between health and behavior, and health and race. At APA, his priorities include bringing psychology's broad expertise to health care, the public, and policy-makers and expanding the role of psychologists in our nation's health care system, the workplace, and education.

Prior to joining APA, Dr. Anderson was Professor of Health and Social Behavior at the Harvard University School of Public Health, where his interests centered on health disparities and mass media approaches to public health. He is also widely known as the first Associate Director of the National Institutes of Health (NIH) for Behavioral and Social Sciences Research, and the first Director of the NIH Office of Behavioral and Social Sciences Research (OBSSR). At NIH, he was charged with facilitating behavioral and social sciences research across all of the (then) 24 institutes and centers of the NIH. Under his purview was behavioral and social research in such areas as cancer, heart disease, mental health, diabetes, aging, and oral health.

Prior to going to NIH, Dr. Anderson was Associate Professor in the Department of Psychiatry and

Psychology: Social and Health Sciences at Duke University. There he studied the role of stress in the development of hypertension in African Americans and directed the NIH-funded Exploratory Center for Research on Health Promotion in Older Minorities. He received several awards for his research, including the 1986 New Investigator Award from the Society of Behavioral Medicine, the 1991 Award for Outstanding Contributions to Health Psychology from the APA, and a Research Scientist Development Award from the National Institute of Mental Health.

Dr. Anderson is a Fellow of the APA, the American Psychological Society, the Society of Behavioral Medicine, and the Academy of Behavioral Medicine Research, and he is a Past President of the Society of Behavioral Medicine. He has served as President of the Board of Directors for the STARBRIGHT Foundation of Los Angeles. He has also served on the Advisory Committee for Public Issues for the Advertising Council and chaired the National Academy of Science's Panel on the Future of Research on Race, Ethnicity, and Health in Later Life.

Dr. Anderson has published widely in the field of health and behavior and is author or editor of several books, including *Emotional Longevity: What Really Determines How Long You Live* (2003).

---

## ACCULTURATION AND HEALTH

---

The term *acculturation* has been used to describe the changes in cultural attitudes, values, and behaviors that occur upon contact between two formerly autonomous population groups, such as a colonized and a colonizer group, or an immigrant group and its host society. It is often assumed that only the culture of the subordinate (minority) group changes, while the culture of the dominant (majority) group does not change. However, some acculturation studies do acknowledge the bidirectionality of acculturation, that is, that both the minority and the dominant culture may change upon contact with one another (Redfield, Linton, & Herskovits, 1936; Social Science Research Council, 1954)

It has been noted that among immigrants, acculturation shows an association with health outcomes. This finding, along with the centrality of acculturation in the immigrant experience, has heightened interest in studying the effect of acculturation on health.

Importantly, the concept of acculturation refers both to how acculturated an individual is (acculturation as an outcome) and to the process through which an individual acquires the values, norms, and behaviors of the host culture (acculturation as a process). It has been hypothesized that both the degree of acculturation an individual has attained and the acculturation process he or she undergoes may affect health outcomes.

In the United States, acculturation has been examined primarily in relation to the health outcomes of immigrants. However, some studies have focused on

nonimmigrant minority groups such as African Americans, Native Americans, and Puerto Ricans. Here we discuss the research on immigrants since it constitutes the bulk of the U.S. literature on acculturation and health.

### ACCULTURATION AND ASSIMILATION THEORIES

Acculturation theory originated in anthropology in the 1930s. Anthropologists were originally interested in the changes experienced by colonized cultures upon contact with colonizer (i.e., dominant) cultures. Therefore, most anthropological research on acculturation has been conducted abroad. A new development in the field is the study of immigrants in the United States (Foner, 2000). Although health research has applied the anthropological concept of acculturation to the study of health outcomes among immigrants in the United States, it generally lacks a strong theoretical foundation. Critics have noted that acculturation is rarely defined in the health literature (Gutmann, 1999; Hunt, 1999).

Acculturation, defined as learning the language and cultural normative lifestyles of the host country, has been conceptualized as the first step toward assimilation, which also involves socioeconomic advancement, intermarriage, and the absence of prejudice and discrimination in the core society (Gordon, 1964; Portes & Rumbaut, 2000; Rumbaut, 1996). The classical sociological theory of assimilation predicted that immigrants would be absorbed into the mainstream of the host society. Recent theoretical developments in sociology (i.e., segmented assimilation theory) have

questioned the inevitability of assimilation into the mainstream, and proposed that integration is only one of several possible assimilation outcomes. These outcomes, which vary across immigrant groups, also include downward assimilation and biculturalism (Portes & Rumbaut, 2001).

Health research has focused on the role of acculturation (i.e., English-language acquisition, changes in values and norms) as opposed to structural assimilation. Only recently, a few health studies have begun to address socioeconomic factors, contextual factors, and discrimination in the host society along with acculturation (Arcia, Skinner, Bailey, & Correa, 2001). For instance, Harris (1999) examined whether family and neighborhood factors mediated the positive association between immigrant assimilation and poor physical/mental health and health risk behaviors. Finch, Kolody, and Vega (2000) showed that perceived discrimination and acculturative stress have independent effects on depression among Mexican-origin adults in California.

The focus on acculturation (as opposed to assimilation) in health research may be due to the link between acculturation and behavioral perspectives. Acculturation has been defined as behavioral assimilation. Health research has favored health behavior models, which emphasize the role of individuals in making lifestyle choices that are conducive to good health (Krieger, 2001). Health research on acculturation assumes that culturally based differences may explain differences in health behaviors among individuals from different ethnic groups (Hunt, 1999).

## ACCULTURATION AND HEALTH OUTCOMES

The role of acculturation has been examined in relation to diverse health outcomes including health behaviors (e.g., tobacco/alcohol use, unsafe sex practices), access to preventive health care (e.g., prenatal care, immunizations, dental care), health beliefs/attitudes (e.g., parenting beliefs), and infant/child health (e.g., low birth weight, infant mortality). A search on Medline conducted in June 2002 using "acculturation" as a MeSH subject heading generated 1,630 citations (1966-June 2002).

It has been noted that acculturation seems to have a detrimental effect on health outcomes, that is, more acculturated immigrants exhibit worse health outcomes than their less acculturated counterparts. For

example, this positive association between acculturation and poor health has been documented for alcohol use (Caetano & Mora, 1988), smoking (Perez-Stable et al., 2001), illicit-drug use (Amaro, Whitaker, Coffman, & Heeren, 1990), low birth weight (Cobas, Balcazar, Benin, Keith, & Chong, 1996), and immunization rates (Anderson, Wood, & Sherbourne, 1997). It should be noted though that a number of studies have found a negative association, no association, or a U-shaped association between acculturation and poor health.

Why is acculturation detrimental for some health outcomes? Some researchers have hypothesized that "immigrant status" (Harris, 1999) or a specific "cultural orientation" (e.g., Mexican; Scribner & Dwyer, 1989) may confer a protective effect on health. There are mechanisms by which increased acculturation may worsen health (e.g., via reduced social support as recent immigrants may have stronger social networks). However, there are also mechanisms by which acculturation may improve health (e.g., through better access to health care as immigrants' chances of having health insurance may increase with length of stay in the United States). The possible mechanisms by which acculturation may influence health outcomes are often not discussed or tested in the literature.

Various outcomes show different associations with acculturation. For instance, while several studies found that acculturation is a risk factor for smoking (Perez-Stable et al., 2001), others showed that access to health care improves with increased acculturation (Solis, Marks, Garcia, & Shelton, 1990).

Also, for a given outcome the association with acculturation often varies by ethnic/national origin group. For example, acculturation seems to be positively associated with tobacco use among Hispanics (Perez-Stable et al., 2001). Among Asian subgroups, studies have reported both a positive (e.g., among Chinese; Chen, Unger, & Johnson, 1999) and a negative (e.g., among Vietnamese; Wiecha, Lee, & Hodgkins, 1998) association between acculturation and smoking.

As noted earlier, acculturation refers to both a process and an outcome. Some studies have focused on the stress associated with the process of acculturation. For example, Perez (Perez M, Pettit, & Joiner, 2002) showed that the interaction between acculturative stress and body dissatisfaction predicted bulimic symptoms.

## ACCULTURATION AND THE HISPANIC PARADOX

Overall, researchers have found a positive correlation between socioeconomic status and health outcomes. Although Hispanics tend to be poorer, less educated, and medically underserved compared with non-Hispanic Whites, they often have similar health outcomes. The term “epidemiologic paradox” refers to this unexpected finding.

It has been hypothesized that the Hispanic paradox may be attributed to the protective effects of immigrant status, which may be mediated by acculturation. Several studies have found more favorable pregnancy and infant mortality outcomes among foreign-born mothers of Hispanic descent than among U.S.-born mothers of Hispanic descent (Franzini, Ribble, & Keddie, 2001). Scribner (Scribner & Dwyer, 1989) proposed the “acculturation hypothesis” suggesting that a group-level effect for cultural orientation is more important in determining the risk of chronic disease among Mexican Americans than genetic, biological, or socioeconomic factors at the individual level.

## INTERACTION BETWEEN ACCULTURATION AND DEMOGRAPHIC AND SOCIOECONOMIC FACTORS

Some studies have examined whether the effect of acculturation is explained or modified by other factors.

### Gender

Research has shown that the effect of acculturation on health is different for males than for females. For instance, it appears that acculturation increases the risk of smoking more among females than among males (Epstein, Botvin, & Diaz, 1998; Marin, Perez-Stable, & Marin, 1989; Shankar, Gutierrez-Mohamed, & Alberg, 2000). These findings are consistent with some sociological studies that suggest that acculturation is a gendered process. Immigrant girls are more likely than immigrant boys to have hyphenated ethnic identities (e.g., African-American, Hispanic-American), to experience low self-esteem and depression, and to have conflict with their parents (Rumbaut, 1996).

## Socioeconomic Status

The evidence on whether acculturation has an effect on health after taking into account socioeconomic status (SES) is mixed. For example, Prislin, Suarez, Simpson, and Dyer (1998) found that even after accounting for SES and demographic factors, more acculturated Mexican women in Texas are less likely to have their children adequately immunized. Some studies have suggested that acculturation may interact with SES. For example, education may have a protective effect among more acculturated individuals but not on less acculturated individuals.

## Access to Health Care

In several studies, access to health care appeared to be positively associated with acculturation (Ismail & Szpunar, 1990), even after controlling for health insurance status, which suggests that either English-language proficiency or increased familiarity with the U.S. health care system may be at work.

Other research found that access to health care (having a routine place for health care, health insurance coverage, and a regular provider) may account for the effect of acculturation on health (Solis et al., 1990).

## ACCULTURATION MEASURES AND SCALES

Operationalizing and measuring acculturation in health research has been elusive. Researchers rely on proxies for acculturation such as immigrant generation status, length of stay in the United States, and English-language use. The use of proxies for acculturation may be problematic. For instance, when immigrant generation is used as a proxy for acculturation, the finding that second-generation immigrants (i.e., U.S.-born individuals of foreign-born parents) have worse health outcomes than first-generation immigrants (i.e., foreign-born individuals) is interpreted as an indication that acculturation has a detrimental effect on health. An alternative explanation, though, may be that first-generation immigrants are selected for good health.

Instead of relying on demographic proxies for acculturation, some studies have used acculturation scales. One of the better-known acculturation scales developed for health research is Hazuda's, which is

divided into five acculturation subscales (covering English-language use and presumed Mexican cultural values) and two “structural assimilation” subscales (covering ethnicity of social networks) (Hazuda, Stern, & Haffner, 1988). Also, a few acculturation scales have been developed for Asians (e.g., Southeast Asians; Anderson et al., 1993; and Filipino; dela Cruz, Padilla, & Butts, 1998).

## LIMITATIONS OF ACCULTURATION AND HEALTH RESEARCH

In the United States, generally, nationally representative health surveys have only limited information on immigrant status (Loue & Bunce, 1999). In addition, most health surveys are cross-sectional, which limits researchers’ ability to examine the process of acculturation. There are very few nationally representative longitudinal health surveys with information on immigrant status (the Adolescent Health Survey is one of them).

To date, only a few U.S. national health surveys have included acculturation scales. The 1982-1984 Hispanic Health and Nutrition Examination Survey (HHANES) included an acculturation scale composed of eight items covering language use/preference, ethnic identification of self and parents, and birthplace of self and parents. In 1987, 1992, and 2000, a cancer supplement questionnaire administered to an adult subsample of the National Health Interview Survey (NHIS) included the same questions on Hispanic acculturation as the HHANES.

Often studies of acculturation and health focus on a single state/community, a single national origin/ethnic group, and/or convenience samples. Therefore, the resulting empirical evidence is fragmentary.

Rarely do acculturation and health studies control adequately for SES and access to health care at the individual level, and even more rarely for family and neighborhood factors. Instead of acknowledging these data limitations, residual effects are often attributed to “culture.” A similar problem exists in relation to English use/proficiency variables, since it is unclear whether the effect of English-language use/proficiency should be interpreted as a cultural factor or as an access factor.

Different associations between acculturation and health outcomes have been documented for various national origin groups. However, acculturation and health research has not adequately addressed whether

the causes of these variations across immigrant groups are due to socioeconomic, cultural, or contextual factors. Further research on the role of gender in moderating the effect of acculturation on health is also warranted.

Finally, critics have noted that in health research, acculturation is assumed to be a unidirectional process (i.e., only the minority culture is influenced by the hegemonic culture). Biculturalism is largely ignored, although in other disciplines, for example, sociology, recent theories such as segmented assimilation postulate that it may have a protective effect. Furthermore, in health research, acculturation is implicitly taken to represent modernization. Two analytically separate cultures are assumed: the mainstream one (modern) and the ethnic one (traditional). Health behaviors based on rationality/responsibility are ascribed to the mainstream culture, while behaviors based on irrationality/irresponsibility are ascribed to “ethnic” cultures (Gutmann, 1999; Hunt, 1999).

## ADHERENCE TO TREATMENT REGIMENS

Adherence, also known as compliance, to treatment regimens refers to the degree to which a patient's management of his or her daily regimen corresponds to the regimen prescribed by the health care provider. Thus, if a patient is prescribed one pill twice a day and takes one pill twice a day, the match between behavior and prescription is 100%—adherence is 100%. If that same patient takes one pill once a day, the match is accurate 50% of the time—adherence is 50%. Similarly, if the patient is prescribed exercise three times a week for 30 minutes but exercises once a week, that patient would be 33% adherent.

Problems with adherence to treatment regimen have been known for centuries. Indeed, Plato commented on poor adherence to recommended treatment based on observations made while accompanying his physician brother on patient visits. Efforts to study adherence to medical treatments began in earnest in the late 1960s, with studies of interventions beginning in the mid-1970s. The first conference on patient adherence (compliance) was held in Canada in the mid-1970s. Since that time considerable effort has gone toward understanding this phenomenon and to a lesser extent to exploring strategies to remediate it.

Adherence problems may arise with any treatment regimen. Indeed, adherence rates to medication, diet, and exercise regimens have all been reported to average about 50%. This reflects substantial deviation from optimal therapies, a deviation that results in more than \$150 billion in added costs annually (Grahl, 1994); the added costs are the result of additional treatment requirements, preventable hospitalization, management of disabilities, and the burden of early retirement.

In addition to added costs to the health system, poor adherence may have significant negative clinical consequences. Poor adherence has been associated with disease progression and with the development of

complications. It has even been associated with loss of transplanted organs and death. Furthermore, poor adherence has been associated with the development of treatment-resistant organisms in such conditions as HIV/AIDS, ear infections, and tuberculosis. Failure to adhere to immunization recommendations has been associated with preventable disease, such as measles. Undetected poor adherence prevents the assessment of treatment adequacy and clinical efficacy. This often results in changes in treatment or in treatment dosing.

Poor adherence not only has a negative impact on clinical outcomes, it also has a negative impact on clinical trials. When subject adherence is low in research, larger sample sizes are required to provide adequate power to evaluate treatment efficacy. This can significantly increase the cost and time to complete studies. Where this compensation is not done, treatment effectiveness may be underestimated. Poor adherence may reduce the ability to detect side effects from treatment, thus overestimating safety and/or underestimating risks or adverse effects. Thus, poor adherence has the potential to mask true evaluations of new treatments, thus impacting treatment itself.

## PATTERNS OF POOR ADHERENCE

Deviation from the prescribed treatment, or poor adherence, may take many forms. First is the failure to initiate the regimen at all. Multiple reasons account for this decision. Patients may not believe in the necessity or effectiveness of the treatment or may not believe that they need treatment at all. Other patients worry about the risk of side effects or adverse effects. Still others are concerned about the costs of treatment or its accessibility.

A second form of deviation from treatment is stopping a treatment too early. Multiple reasons account for this behavior. Patients may stop treatment because they feel better or believe that they no longer need treatment. Others may stop because of the accessibility of continued treatment. Still others may experience untoward effects associated with the treatment. An additional factor is a lack of clear understanding of the need to persist with treatment.

Other patients may not stop the treatment altogether, but may miss doses of treatment. This is perhaps the more common form of poor adherence. Treatment may be missed episodically or the patient shows a predilection for certain doses to be omitted. For medication this may be reflected in certain times

of day or certain days of the week. For example, medications to be taken at lunchtime or during social events or on weekends have a higher risk of omission. For dietary programs certain meals or days may be most at risk. Days of the week may also be a factor in missed exercise episodes. Missed episodes may lead to whole days or sets of days without treatment. If three consecutive days or more are missed, the period is referred to as a holiday. The most commonly reported reasons by patients for such episodes include forgetting, disruptions in the routine, irregular lifestyles, busyness, and inconvenience, particularly for medication management. Alterations in routine, busyness, distractions, inconvenience, time required, social situations, inadequate knowledge, lack of awareness, and side effects have all been reported by patients as contributors to errors in regimen management. Other factors may play a role as well, such as the belief that periods off treatment are beneficial or that less treatment than that prescribed is sufficient.

Patients may also lower the dose of treatment. They may reduce the number of pills taken or the number of bouts of exercise or the extent to which a diet is modified. Multiple factors influence this action. Patients may not fully understand treatment. The support network may undermine adequate adherence. The patient may feel better on lower doses of treatment. Costs may be lower. Fully participating in treatment may not be convenient or accessible.

Conversely, the patient may also increase the dose of treatment. Extra pills may be taken; overexercise may occur; excessive dietary restrictions may be enacted. Less is known about reasons for overconsumption. For some patients, this may occur to self-manage symptoms. For others, beliefs about treatment may underlie regimen alterations. Not uncommon is taking make-up doses of medication when the patient forgets whether or not medication was taken.

Timing errors represent a common deviation from the prescription. Medication prescribed twice a day may be taken 3 or 4 hours apart with the next dose 20 or 21 hours later. Exercise bouts may be clustered on the weekend rather than distributed throughout the week. A common reason for timing errors is a lack of understanding or information about effective timing. Another reason for this type of adherence problem is the inconvenience of carrying out the treatment at appropriate times.

Perhaps the most common type of poor adherence is a combination of the above problems, leading to an

erratic pattern of adherence. The reasons for poor adherence may change from time to time. Often the patient is unaware of the extent of the problem of poor adherence that is present.

Last, patients may make technical errors that could be conceived of as adherence problems, but might better be labeled as performance errors. For example, a patient with asthma may be prescribed an inhaled medication to be given four times a day, three puffs per time. The doses and the timing may occur correctly, but the patient may be unaware of the need to leave a time between puffs to enhance the effectiveness of the medication. Similarly, patients may make errors in the estimation of portion sizes in efforts to follow a calorie-restricted diet. Often these errors are due to poor understanding or a lack of thorough education by the provider.

Many other factors have been associated with poor adherence. For example, a number of studies have reported that early adherence to the treatment regimen is predictive of longer-term adherence. For the most part, demographic factors have not been predictive of adherence, with some variation from study to study. Social support has been found to have both positive and negative relationships with adherence. Selected health beliefs have demonstrated associations with level of adherence. The data for mood and personality dimensions remain inconclusive, although there are a number of reports that depression and low conscientiousness may be associated with poorer adherence. One of the difficulties in establishing firm associations is that the majority of studies have measured adherence through self-report, a measure that has been found to have significant and biased error. Very few studies have examined factors associated with poor adherence using more accurate measurement of adherence.

## MEASUREMENT OF ADHERENCE

Measurement of adherence has formed a core area of study in adherence. Advances in our understanding can be directly related to advances in measurement. In the 1960s, attention was focused on examination of self-report versus empirical observations. There was interest in the ability of the clinician to identify poor adherence. These studies failed to show that the clinician was able to do this. In the 1970s, increasing attention was given to biochemical assays and to the beginning development of monitors. The biochemical assays were shown to be affected by a host of individual characteristics and not to be particularly informative about adherence, particularly

adherence over time. In the 1990s, increased focus was placed on the development and utilization of a variety of electronic event monitors. Of interest at this time is the accuracy of these measures and their utility in research and clinical practice.

As noted, adherence can be measured in a variety of ways. The most common method over time has been the self-report. When compared with other measures, self-report has been shown to overestimate adherence and to significantly underestimate the number of poor adherers in a population. Self-report may be influenced by the demand characteristics of the research or clinical interaction, the structure of the self-report measure, the tendency to report "good" behavior, failure to remember events, and the tendency to estimate longer-term behavior based on recent behavior.

Other methods of assessment include examination of drug levels or biological indicators, for example, cholesterol levels, weight, and blood pressure. Unfortunately, these clinical indicators do not bear a strong relationship with more accurate measures of adherence nor do they permit an examination of the degree of adherence over time. They are influenced not only by adherence but also by adequacy of the regimen, treatment interactions, metabolism (of drugs), and other individual characteristics. They are not particularly accurate measures of assessing adherence.

The method considered to be most accurate at this time is the electronic event monitor. Electronic event monitors are available for medication taking, dietary recording, exercise, and diary recordings. In at least two investigations, the electronic event records were the only assessment strategy associated with clinical outcomes. This method tends to be more expensive than the self-report or biological assays. It is, however, particularly useful for research studies where greater precision in the estimate of adherence is needed and in clinical situations where there is a concern that a lack of clinical outcome is due to poor adherence but other measures are not detecting it.

## STRATEGIES TO IMPROVE ADHERENCE

Strategies to improve adherence to prescribed regimen have been of interest for nearly three decades. Yet much of the research has been devoted to the study of predictors and to assessment. Limited numbers of studies have been undertaken to examine, through randomized controlled investigations, how adherence

can best be improved. The majority of the work on adherence improvement has been done in the area of medication taking, where more than 500 investigations have been reported. Just 33 of these trials met adequate research design criteria (randomized clinical trial) and examined both adherence and clinical outcome over a 6-month or longer period (Haynes, McDonald, Garg, & Montague, 2002). Nearly half of these reported improvement in medication adherence, using primarily self-report or biological assessment, with 89% of those reporting improved clinical outcome. Studies focused on adherence improvement in behavioral interventions have received limited attention. A major concern regarding the intervention studies is that for the most part measurement of adherence has been through self-report.

The strategies that have been examined have had little impact on the population of patients in clinical care. The rates of adherence have changed very little in the nearly 30 years that intervention research has been conducted. This may be for a variety of reasons. The effect sizes of intervention studies are not large. The use of less accurate outcome measures may steer practice in erroneous directions. Issues of translation to practice sites have not been adequately addressed.

Even though there is a need for further testing of adherence intervention strategies, there are general measures that can be derived from the studies that have been done that appear useful: tailoring the regimen to patient routines, ongoing contact, adequate instruction in the treatment, self-monitoring, and the use of varying reminders. Continued research will help refine these and suggest new strategies.

## SUMMARY

There has been a substantial investment in adherence research by clinicians and researchers over the past 30 years. Yet, as noted, there is a considerable amount of knowledge to be gained from further study. The significance of the problem suggests that it is important to pursue that added knowledge. Refinements in measurements, increased specificity in predictors or correlates, and testing of new interventions show promise in improving a problem that affects approximately one half of patients in clinical care.

## ADOPTION OF HEALTH BEHAVIOR

---

*Health behaviors* are personal acts that raise or lower the risk of illness or injury. Behaviors that are performed predictably and often are called *habits*. Psychologists seek to understand health habits by viewing them as organized *systems*, composed of highly routinized sequences of actions, consequences, and reactions that lead to a predictable result. For example, dietary habits involve frequently practiced routines, each of which consists of a familiar sequence of behaviors, such as shopping for groceries, planning and preparing meals, and enjoying food in family or other settings. These routines can be viewed as consisting of functional feedback loops in which each behavior in the sequence is strengthened by the consequences it produces, and those consequences, in turn, then set the stage for the next behavior. In the present example, the act of leaving work and stopping at a grocery store on the way home is reinforced by the satisfaction of gathering needed food items, which then enable the hungry shopper to prepare a meal.

Preparing and sharing a meal often are accompanied by other activities, such as enjoying the company of friends or family members, which, by increasing the pleasure of eating, may lead to overindulgence. Efforts to alter diet or curb overeating must identify new actions and new outcomes to replace the usual eating routines.

Health behaviors tend to become *habitual* when they produce effects that are felt to be positive, are experienced reliably and often, and mesh with the routines of other persons with whom one interacts. Therefore, the most effective way to eliminate a health-damaging habit is to replace it with a health-protective habit that can occur in the same setting, requires similar or less effort, yet produces comparable effects. The first step in health behavior change involves analyzing a health-damaging habit in terms of its action system components (settings, actions, consequences) and identifying an alternative habit and action system components to encourage in its place. For example, those who want to lose weight by limiting consumption of high-calorie snacks might be advised to start by analyzing where, when, how, and why they snack and then to identify low-calorie snacks that could be consumed in the same situations, in similar ways, and with comparable levels of enjoyment.

Here we uncover the Achilles' heel of health promotion: A failure to experience a desired benefit fairly soon after performing a new health behavior lowers the likelihood that the new behavior will become a habit. The great and enduring challenge in health habit change is to ensure that desired consequences will be experienced, immediately and often, whenever and wherever the desired health behavior is performed.

The interpersonal environment plays an important role. Negative reactions by friends or family members can make it difficult to establish new health-protective patterns. The degree of "action linkage," or the extent to which two people's routines are interconnected, determines how disruptive the behavior change will be for both, and thus how difficult it may be to sustain the routine over time.

So how do people change their habits? It is one thing to know what one should do. But making a sustained effort to change is quite another matter. Several decades of research suggest that the process of change involves enhancing self-motivation, personal competence, and social support (Ewart, 1991, 2003).

People do not achieve sustained health habit change unless they believe that change is beneficial,

are capable of taking the necessary actions, and view habit change as compatible with important personal strivings or projects. Motivation to alter dietary habits derives, in part, from the judgment that eating differently will improve health or personal appearance and that such outcomes are desirable. These expectations may be enhanced through social modeling and exposure techniques. In the former, people are shown examples of individuals similar to themselves who enjoy the benefits of healthy behavior, or who suffer the ill effects of unhealthy habits. Direct exposure involves having the individual experience an outcome directly, as when children are given tasty fruit snacks to encourage their interest in healthy nutrition.

In addition to believing that a behavior change would be beneficial, people must feel personally capable of taking steps needed to achieve change. *Self-efficacy* refers to a person's level of confidence that he or she can take the necessary steps. Self-efficacy can be increased by performing an unfamiliar or difficult activity in gradually increasing doses, by observing people like oneself successfully perform the behavior, by verbal encouragement, and through interventions to manage physiological stress responses in challenging situations (Bandura, 1997).

A third motivational factor involves personal goals and strivings that shape one's day-to-day activities. These often involve life tasks such as achieving independence, establishing supportive relationships, pursuing a career, caring for children, maintaining a certain lifestyle, or coping with debility in old age. People are more likely to view a health behavior as desirable and feasible if the behavior is congruent with important personal strivings. Barriers to self-change can be lowered by helping people alter their projects and priorities. This may be achieved by identifying important strivings, clarifying ways in which different strivings or projects may conflict with one another, and considering how projects and health behavior changes might be made mutually supportive.

Why do attempts at self-motivation often fail? Even people who are highly motivated may fail to succeed in changing their habits if they do not formulate appropriate goals and plans. Motivational appraisals often fail to generate long-term change because people do not take the time to think through what they are trying to accomplish, anticipate difficulties, devise solutions, create plans, and set attainable goals. Therefore, in addition to motivation, self-change requires careful planning, problem solving,

and goal setting. People must learn to think flexibly and creatively about how to define the various challenges, anticipate difficult situations, brainstorm solutions, devise appropriate plans, and set attainable goals. Much of the difficulty in sustaining a new health habit over time involves remaining alert to potential problems, generating workable solutions, making plans, and setting goals.

These tasks call for two types of social competence. One type of competence involves knowing what one should do and why, whereas the other type of competence consists of practical know-how, or skill in performing specific actions needed to produce a desired effect. Together, these forms of competence enable one to comprehend, organize, retrieve, and apply information needed to make appraisals and solve problems.

Health education programs traditionally emphasized the teaching of health and illness "facts." Yet these efforts often failed to build practical behavioral skills that enable people to make decisions and act on their appraisals of the facts. Educational interventions must identify the types of behavioral skills that people will need when trying to implement their self-change plans.

Coping with relationship problems that result from habit change calls for *relational competence*, which involves partners' ability to understand and validate each other's goals and projects, and their willingness to manage conflicts either by coordinating goals (e.g., taking turns), compromising (e.g., each gets part of what they want), or resolving the conflict at a higher level. For example, the people involved may decide to focus on a shared, higher-order goal, as when partners agree to disagree on some issue in order to achieve harmony on matters of larger concern to both. Mutual understanding and validation are facilitated by communication skills such as reflective listening, sharing of feelings, and problem solving and are impeded by maneuvers designed to silence or hurt the other partner, and by withdrawal. Relationship-focused training in communication and problem-solving skills may be needed to help support the behavior change process.

How does the wider social environment affect people's ability to change patterns of behavior that affect their health? A person's social and economic status, education, and community environment have a major effect on health, in part because these factors affect one's ability to adopt new health behaviors (Gallo & Matthews, 2003). Neighborhood disorder,

crowding, violence, noise, temperature, and pollution have a variety of direct and indirect effects on people's capacity for self-protective action. These proximal environmental stressors and barriers threaten to disrupt the development and maintenance of self-protective health habits. Such environmental stress may deplete personal energy, reduce access to health information, and limit opportunities to engage in healthy pursuits such as regular physical exercise (Ewart & Suchday, 2002).

Community norms also play an important role in shaping health behavior. Norms function as rules of thumb that indicate the kinds of things one should do, or avoid doing, in pursuing one's goals. It is important, however, to distinguish between *perceived* norms and *actual* norms. People often base their actions (at least those actions that are publicly visible) on how they think others would behave, thereby conforming to a *perceived* norm of conduct, or public opinion. But the perception may not be accurate. Others may not support the perceived norm, or they may conform to it publicly while not endorsing it privately. This opens the possibility of influencing people's actions by altering their perceptions of publicly endorsed behavior codes, norms, and opinions.

Interventions to modify health behavior by altering social norms—or people's awareness of norms—have enjoyed some measure of success as components of educational programs to curb excessive alcohol use or discourage unsafe sexual activity. These interventions operate in part by altering perceived “public” norms for behavior in potentially unsafe situations.

Social networks and settings also influence individual behavior by exposing people to social models whose actions convey information about behavior-outcome contingencies, by providing opportunities to develop and sustain supportive relationships (i.e., to acquire relational competence), and by influencing biological conditions that facilitate or constrain action.

How does biology affect people's ability to change health habits? Biology can influence the adoption of health behavior by affecting personal and relational competence, and thereby shaping the ways people view their personal projects, perceive outcomes, appraise their capabilities, solve problems, and set goals. Biological influences include physical conditions such as fatigue or illness and states induced by the consumption of alcohol or other substances, as well as biologically based dispositions that are evident from birth as temperamental differences in activity, sociability,

and impulsivity. Together, biological and social influences combine to influence mood states, which can affect susceptibility to emotions such as fear, anger, sadness, joy, or pride, and thereby enhance or impede one's motivation to change. Negative emotions, as well as states of intoxication, may interfere with one's ability to recall health information, to envision effective forms of action, to judge the potential consequences of their actions, or to solve problems and envisage appropriate behavioral goals. Positive emotions, on the other hand, may enhance these activities. People who are emotionally distressed also have difficulty developing and maintaining close supportive interpersonal relationships that may facilitate self-change.

By now it should come as no surprise that there are a lot of questions about how best to improve the health of the public by helping people change their lifestyle habits. Many questions involve the process of change; for example, individuals differ in their readiness to change, and those who achieve success often do so after repeated failures. Some health psychologists would divide the process of change into a sequence of distinct stages, whereas others argue that the notion of fixed stages is not a valid or very useful concept. Other questions concern the relative feasibility and effectiveness of interventions that empower individuals to protect their own health, as opposed to interventions that reduce the need for personal self-protection by creating healthy environments.

Finally, there are many different theories and models of health habit change (Schneiderman & Speers, 2001). What is one to make of this conceptual profusion? Are controlled experiments needed to compare the various models, identify the best, and narrow the field? Or is such diversity appropriate, considering the multifaceted psychological, biological, social, and political dimensions of the behavior change process? Do we need a theory about how to evaluate, organize, and integrate the various health behavior theories (Ewart, 2003)? These questions and many others promise to keep behavioral scientists very busy in the years ahead.

## AFRICAN AMERICAN HEALTH AND BEHAVIOR

---

Over recent years, there has been an increasing recognition that behaviors, as well as the environmental contexts in which they are exhibited, are important to the conceptualization of the health of African Americans. Studies have begun to explore the dynamic relationship between behavior and health in an increasing number of diseases including cancer, diabetes, and asthma, while constantly integrating an increasing number of behaviors (smoking, eating, exercise, etc.). Few studies, however, have integrated into their conceptualization and empirical explorations the full range of contributory sociodemographic factors such as age, gender, race, and even psychosocial factors such as coping. Of these, race has certainly risen as one of the more complicated factors to define and evaluate. In particular, research on African Americans is often conducted with poor and unreliable operational definitions, and is conceptually void of an appreciation for the history and context of many of the behaviors that are frequently described. The current entry is designed to provide a brief historical context from which to better understand behavior in African Americans as it directly relates to health.

## HISTORY AND CONTEXT

The term *race* has historical roots in distinguishing humans based on ancestry and physical characteristics. *Race* is most often used to distinguish a population based on biological factors such as genetics, common descent, and physical appearance. For example, the Caucasoid race is often characterized as pale pinkish white to olive brown in skin color, of medium to tall stature, with a long or broad head, and of European ancestry. The Mongoloid race is often characterized as saffron to yellow or reddish brown skin color, of medium stature, and a broad head with Asian ancestry. The Negroid race is characterized by brown to brown-black skin, usually with a longer head, varying statures, and thick everted lips and African ancestry. Historically, race has been viewed as either a convenient mechanism for social and political classification or a useful and distinctive term that conveys salient information about biological predispositions and behavioral characteristics. More recently, the utility of *race* as representing distinct variance among groups of humans has grown into disfavor as having extremely limited utility, as not identifying unique intragroup genetic variance, and having limited scientific value. Many epidemiologists have suggested that *ethnicity* (biology + behavior + culture) may be a more accurate term.

The importance of race, particularly in American society and as exemplified by how we manage the construct, has undergone several distinct transitions over the years, but can be grossly divided into three eras. From the period beginning with slavery and extending into the 1950s, race was used as one of the most distinguishing characteristics of humans. Having a single drop of "Black" blood (any Black ancestors) was sufficient to identify a person as Black (one drop rule). During this time, very limited attention was placed on studying African American health because they were considered of little importance. Early medical researchers often failed to include African Americans because they were considered animalistic, property, and second-class citizens, if citizens at all. When they were included in research, they were treated as if their capacities were equal to or less than animals. Consent was almost never obtained and there was little regard for their comfort or long-term impairments including death resulting from experimentation. Race was thought to be associated with stereotyped genetic, behavioral, cognitive, and emotional

characteristics. For practical purposes this time is characterized as the “race is everything” era.

By the mid-20th century, culturally, America was initiating its journey toward equality of disposition and access. With the growth of the civil rights movement, America began to recognize that humans were born equal and that the concepts of “superiority” and “inferiority” were sociocultural constructions with little if any biological support. This recognition later led to an active and convenient minimization of the differences among races, due in part to a misassumption that “equality” and “same” were equivalent. The biopsychosocial functioning of Caucasians was thought to be the gold standard, and the degree to which individuals deviated from or were similar to this standard was the representative degree to which they were considered “normal” or “abnormal.” During this era, biomedical researchers again primarily focused on Caucasians with little emphasis on representing minorities and their uniqueness (African Americans, women, children, etc.) in studies. Consistent with the sociocultural activity of that time, research tended to downplay racial differences, if race was mentioned at all (Keefe et al., 2002). This second period of attention to civil rights and a convenient minimization of race is characterized as the “race is nothing” era.

Beginning in the late 1980s and in the context of a significantly diversified American culture, the importance of having racial and ethnic representation in biomedical research was elevated. Federally funded institutes began mandating representative samples, and the zeitgeist of the society shifted to recognize that humans could be different and alike, simultaneously. Furthermore, based on evidence from the human genome project and technological advances that allow for the detection of differences and similarities in genetic codes within humans and across other species, the recognition that “racial” groups may share more biological variance between them as compared to within them became popular. At the same time, it was also recognized that people have differences that are noteworthy and that these differences may contribute substantially to health outcomes.

During this era of “enlightenment,” American society also began to recognize the importance of understanding health in a more comprehensive context of historical experiences, psychosocial dispositions, and cultural influences in addition to biological factors. Consequently, to study health in African Americans,

and similarly Caucasians, is to study a system of behavior, thought, and emotion that is influenced by environmental interactions, historical experiences, and cultural forces.

The present entry will highlight this complex system of behavior, thought, and emotion using a cognitive-behavioral frame as it relates to disease in African Americans.

## HIV/AIDS

The prevalence of HIV/AIDS in African Americans is clearly different from other U.S. populations. African Americans account for approximately 38% of all AIDS cases reported in the United States, despite comprising only about 12% of the U.S. population. The rate of infection also appears to be higher among African Americans as compared to others, with a rate 8 times as high as the rate for Caucasians in the year 2000, and twice as high as the rate for Hispanics.

Many have postulated that since the prevalence of HIV is different among African Americans than among Caucasian Americans, risk behaviors must be different, and prevention efforts must also be different. Unfortunately, little is known about the behaviors most associated with the transmission of HIV in African Americans. It is, however, known that since the AIDS epidemic began, 37% of AIDS cases among African American males were the result of homosexual contacts, 34% were due to injection drug use, and 8% were due to heterosexual contact. Among AIDS cases reported in African American women, 41% were among intravenous (IV) drug users, and 38% were attributed to heterosexual contact.

Prevention efforts for minority populations are further made complicated because the course of exposure is often unknown. While the leading exposure category among men of all other ethnic groups is homosexual contact, the leading exposure category among Black men is “unreported” or unknown risk.

Recently, many researchers, community and political activists, and patients have asked if the increased prevalence of HIV/AIDS in African Americans is a failure of African Americans to alter their behavior in a fashion to reduce risk or a failure of scientists to understand African American behaviors in a context that allows for the development of better prevention programs that ultimately reduce risk. While knowledge about AIDS has been attributed to decreased risk, racial minorities demonstrate less knowledge

about AIDS than do other populations. In its essence, a single system of prevention appears not to work for all communities. Many speculate that African American-specific programs may be needed to reduce the prevalence of this epidemic in African Americans. These programs may focus on presenting information in a context (maybe through churches and community organizations rather than from doctors, etc.) that African Americans trust, understand, and then can respond to, resulting in a change in risk behaviors.

The cognitive-behavioral model posits that thoughts precede emotions and behaviors. Consequently, thoughts and attitudes of African Americans become a target of scientific exploration when behavioral change and risk reduction for HIV/AIDS is desired. Since the vast majority of all HIV transmission is through sexual contact or shared illicit drug needles, prevention programs have depended, and maybe detrimentally so for African Americans, on social support factors and peer pressure as the basis of incidence reduction. However, the nature and importance of social support and peer pressure may vary across races/ethnicities and cultures, and consequently, the effectiveness of social and peer pressure techniques may also differ in effectiveness.

Few studies have explored the role of social support and peer pressure on health outcomes among African Americans, although there is evidence from other disciplines that social support is differentially experienced and valued as a function of race/ethnicity. For example, Killough, Webster, Brown, Houck, and Edwards (2003) recently found that the social factors that are most associated with academic success in young Caucasians (peer support, social support from friends, peer context, etc.) are, in fact, negatively related to academic success in African American youth. The family context, which is predictive of academic success in African Americans, is negatively associated with academic success in Caucasian youth. This study is suggestive that environmental factors may differentially exert influence on behavior as a function of race/ethnicity, and it provides a basis from which to explore such effects as they relate to health outcomes in African Americans and Caucasians.

Once an individual becomes infected with HIV, diagnostic process and treatment effectiveness may also vary by ethnicity. Treatment compliance with medical directives, which is often directly related to willingness to pursue treatment, is highly related to the conceptualization of "disease" within a race or

culture. For example, some view the contraction of HIV as a punishment for "sinful" or "inappropriate" behavior. An increasing number of individuals with this mindset are having unprotected sexual intercourse or may share infected needles as a mechanism to exert control over when and where they will be "punished" with this "inevitable" disease. Others view HIV transmission as a more random event, and only partly dependent on their behaviors. Yet others may attribute disease contraction and progression to their behaviors and their behaviors alone. It is obvious that such diverse conceptualizations of HIV transmission (cognitions), which often correlate with racial and cultural group membership, influence prevention behaviors, and consequently, risk of HIV/AIDS. Understanding the demographic and other characteristics of individuals who may be at highest risk for infection due to their cognitions and beliefs may be an effective tool for reducing the incidence of HIV.

The willingness to pursue medical treatment and to follow medical directives is often also dependent on the capacity to trust the professional providing medical care. Experiments such as the Tuskegee Syphilis Study, which was perpetrated by Caucasian physicians in a community medical setting on African American men, have set a tone for patient-doctor interactions that is often characterized by distrust and skepticism on the part of many African American patients. There is little evidence that this trend will change in the near future, as is shown by the tremendous difficulties associated with recruiting African Americans into clinical trials and clinical research studies. Knowledge of a history of overtly differential medical treatments for African Americans seen at major teaching hospitals prior to the 1980s and current disparities in health outcomes further fuel a sense of distrust for many. Specifically related to HIV and even more damaging to the treating professionals' rapport, many African Americans and other minorities believe that AIDS is a conspiracy perpetrated by the U.S. government in an effort to exterminate African Americans and homosexuals (Klonoff & Landrine, 1999).

These and other myths serve as the basis for many African Americans' interactions with medical professionals. More unfortunately, for those who suggest that African Americans and other minorities are overly and inappropriately paranoid and that they should just "get over" their fears, the reality of clinical atrocities and research misrepresentations and abuses against African

Americans at the local and national levels remain more horrific than the myths. For many African Americans, distrust, paranoia, and limited utilization of technological advances administered in major medical settings are reactionary and adaptive.

It is impossible to effectively treat African American patients today without consideration for the history, context, and role of African Americans in medical science. Certainly, whether clinicians consider such information or not, minority patients including African Americans do. When treatment is sought in such a poisonous environment, treatment compliance is often diminished by the above discussed beliefs and subsequent behaviors. The interpretation of limited compliance or noncompliance (missed appointments, noncompliance with medical directives, and overt mistrust of the medical profession), thus, among many African Americans must be done in the context of historical experiences and with sensitivity to the relationship between African Americans and the medical system.

Once infected with HIV, occurrence and severity of depression, anxiety, and somatization in HIV-infected persons vary as a function of ethnicity (Lichtenstein, Laska, & Clair, 2002; Heckman et al., 2000), as does subsequent responses to psychosocial treatments (Markowitz, Spielman, Sullivan, & Fishman, 2000). Coping styles are an important factor in the successful management of disease. African Americans and Caucasians differ in their disease-related coping styles; African Americans tend to have a larger percentage of family members in their support networks, and are less likely to tell friends of their HIV status, while the opposite is true for Caucasians. Older African Americans tend to rely more on passive coping (prayer, etc.), while Caucasians and younger patients tend to cope in a more active fashion (exercise, diet, etc.). There is evidence that both coping styles are productive in HIV disease management (prayer + exercise); however, exclusive use of either coping style is detrimental to health outcomes.

The disproportionate effect of HIV on African Americans clearly has little to do with race in terms of common biological or genetic descent and much to do with behaviors and sociocultural factors. Whether race and ethnicity are biological constructs is beyond the scope of this entry, but their social consequences are not. Race/ethnicity and the unique variance associated with being African American appear to influence disease outcomes detrimentally when comparing to Caucasians. But what about diseases

that predominantly affect African Americans? Are there examples of health behaviors worthy of highlighting without comparisons to Caucasians? We suggest that sickle cell disease is an excellent model of a condition that affects primarily African Americans and further illustrates health behaviors for the sake of better understanding African Americans.

## SICKLE CELL DISEASE

A major public health issue, sickle cell disease (SCD) affects 1 in 375 African Americans in the United States, and although less common, also affects people of Hispanic, Native American, East Indian, Greek, Italian, and Eastern Asian ancestry. SCD, like many other diseases with a substantial chronic pain component, has most recently been conceptualized as existing reciprocally as the product of biological, psychosocial, and behavioral factors. The acknowledgment of strong behavioral influences on the manifestation and management of SCD-related pain has led to the development and application of several behavioral models for treatment. Sociodemographic factors such as gender, age, education, and socioeconomic status as an index of attained wealth, as well as general psychological factors such as coping style, coping capacity, and social support, have been used to explain differences in disability associated with pain intensity, pain threshold, and pain tolerance, both clinically and in research settings.

Many of these sociodemographic and psychological factors have also been used to explain comorbid diseases and common reactions that often occur in response to unremitting pain including anxiety, anger, frustration, and depression. Of the potential reactions to unremitting pain, depression is the most often identified psychiatric condition among patients with SCD. Although it is not known whether depressive symptoms result from the psychosocial versus the somatic features of SCD, the functional consequences of depression and affective disturbance are negative and well known. It is estimated that as many as one fourth of patients with SCD experience depressive symptoms such as sadness, guilt, hopelessness, and helplessness. These emotional consequences can result in poor self-care, decreased quality of life, and increased disease impact.

Returning to the cognitive-behavioral model, patients with SCD who experience negative thinking about their capacity to manage their pain and disease tend to utilize the health care system more than patients with positive thinking patterns. In addition,

patients who report the most intense negative thinking patterns tend to experience the lowest tolerance for pain. Interestingly, these results have been found in children and adults. As they relates to SCD, psychosocial factors are intimately integrated in and appear to exert differential impact on the experience of pain, and pain on psychosocial functioning. Recognizing that thinking influences behavior, patients with the most negative thinking patterns have the potential for the most negative health care outcomes.

The complicated relationship between depression and SCD-related pain is possibly best illustrated by studies that evaluate the impact of treating depression in patients with chronic pain. Several studies demonstrate that the health condition of patients with SCD, including pain and disability, significantly improves when antidepressant and psychotherapeutic (cognitive-behavioral therapy) interventions were applied. These studies and many others suggest an intimate and reciprocal relationship between behavior, as the product of thinking and affect, and SCD management.

## THE FUTURE

Chronic psychological and social stressors produce biological, psychological, and social responses that are moderated by many factors including coping style and the availability of coping resources. Coping, which is a manifestation of thinking and an influence on emotional states, affects behavior. One coping strategy, John Henryism (JH), which is based on the story of the legendary John Henry, has most recently gained attention as a powerful stress coping strategy often adopted by many African Americans to manage stress associated with social inequities (James, Hartnett, & Kalsbeek, 1983). Even more recently, the relationship between JH and health outcomes has been explored as a possible explanation for disparities among African Americans and primarily Caucasian populations.

JH has traditionally been defined as a strong behavioral disposition to cope actively with stressors. Individuals who exhibit high JH tend to work harder and exert more effort in response to stress. Research has shown that JH has three basic components: (1) efficacious mental and physical vigor, (2) a strong commitment to hard work, and (3) a single-minded determination to succeed. In its simplest terms, JH is a behavioral manifestation of one's efficacy to meet environmental demands through hard work and determination.

Increasingly, JH is conceptualized as a more complex system of coping that includes psychological dispositions that are a function of experiences, beliefs and perceptions, patterns of responses to social contexts, and biological and genetic predispositions to actively cope with stressors. JH may actually be adaptive when sufficient financial, material, and interpersonal resources are available in a socially equitable environment. Thus, for individuals who have access to the appropriate environmental resources, JH, or a tendency toward hard work with a single-minded determination to succeed, may actually lead to positive health, employment, and social outcomes. However, in persons who have little formal education, limited financial and other resources, and consequently a higher susceptibility to the products of social inequity, high effort with a single-minded determination toward success may lead to frustration and disappointment, negative social consequences (failure, etc.), and chronic physiological arousal.

Empirical evidence has demonstrated that high levels of JH, when exhibited in the absence of financial and material resources, have been found to contribute significantly to the etiology of altered physical functioning and negative health outcomes such as elevated blood pressure and increased urine cortisol levels.

There appear to be tremendous opportunities to apply models such as JH to the exploration of health outcomes among African Americans in the future. For example, what is the impact of low and high levels of JH on prostate cancer outcomes in African Americans with and without adequate and available insurance coverage? Does coping, as conceptualized by the JH model, influence outcomes and management in chronic diseases where cure is not an option (chronic low back pain, osteoarthritis, etc.)?

In response to a changing zeitgeist, researchers and clinicians are beginning to reform the scientific literature to better integrate issues of diversity into the conceptualization of disease in African Americans. This evolutionary change promotes debate and guides the training of our clinicians of tomorrow toward the full integration of diversity into conceptualization and treatment of African American patients. This change also influences the clinicians of today to be more adequately responsive to the needs of a constantly changing U.S. demographic. Most notably, in diseases such as HIV/AIDS and SCD, understanding uniqueness associated with African Americans promotes a better understanding of the obstacles to "good" medical care. Furthermore, and particularly in diseases such as

SCD that predominantly affect African Americans, the integration of these factors results in a dramatic change in health outcomes. The challenge for the future appears to be the effective integration of models of diversity into medical care, which include an appreciation for differences in history and context. When applied to other diseases like prostate cancer, osteoarthritis, and Alzheimer's disease whose outcomes may also be influenced significantly by psychosocial factors, dramatic reduction of health disparities may be noted. A paradigmatic shift in scientific theory, training, and practice toward acknowledging shared experiences with an appreciation for uniqueness ensures our continued existence as providers of an effective health service to all populations.

## AIDS AND HIV

---

Approximately 21 years ago, HIV, the virus that causes AIDS, was first identified. Today, the World Health Organization estimates that there are 42 million people living with HIV/AIDS worldwide; 38.6 million of these are adults, 19.2 million are women, and 3.2 million are children under the age of 15. In 2002 alone, 5 million new HIV infections occurred, and 3.1 million people died of HIV/AIDS-related causes. HIV/AIDS is now the leading killer among all infectious diseases, and is ranked fourth among all microbial causes of death. From its identification to the end of year 2002, about 27 million people died from AIDS. It is now the seventh leading cause of death among 1- to 4-year-olds, sixth among 15- to 24-year-olds, and second among 25- to 44-year-olds

in the United States. About 95% of HIV infections are concentrated in developing countries. The first reported cases of AIDS in the United States were identified in 1981.

HIV causes AIDS. Over time, HIV depletes the subset of lymphocytes called T4 helper cells, or CD4+ cells, that are essential in the proliferation of cells necessary for cell-mediated immunity and the production of antibodies that protect us from infections. Without the ability for the body to produce these cells, we are vulnerable to a variety of infections caused by organisms and viruses that normally do not cause disease in individuals. It is these infections that create the symptoms and progression of illnesses that eventually kill patients who have AIDS. The Centers for Disease Control and Prevention (CDC) defines AIDS broadly as the onset of life-threatening illness that occurs as a result of HIV disease that originates with the infection of a person with HIV. Early in the epidemic, AIDS was thought of as the end stage of the disease process. However, since persons who receive an AIDS diagnosis who receive specialized treatments may recover from these AIDS-defining illnesses, receiving the diagnosis of AIDS is no longer necessarily associated with imminent death.

#### WHAT ARE THE STAGES OF HIV?

A person with normal T4 lymphocyte counts typically has approximately 1,000 cells per deciliter of blood volume. A person acutely infected with HIV commonly drops to a level of approximately 500 cells per deciliter. The CDC defines AIDS as all HIV-infected persons who have less than 200 T4 lymphocytes per deciliter of blood, or T4 lymphocytes percentage less than 14% of total lymphocytes. In addition, there are 23 clinical conditions that define AIDS including diseases such as pulmonary tuberculosis, recurrent pneumonia, and Kaposi's sarcoma.

#### HOW IS HIV TRANSMITTED?

There are three basic mechanisms through which HIV is transmitted: unprotected sexual contact, needles and syringes, and mother to child. All of these mechanisms involve an exchange of body fluids. The body fluids involved in HIV transmission are exchanged during sexual activities, injection drug use, blood transfusions, use of blood products, and during pre- and postnatal events. HIV enters the body

through the lining of the vagina, vulva, penis, rectum, or mouth during sex. Worldwide, the highest frequency of HIV transmission is among heterosexuals. In the United States, males make up 80% of all AIDS cases. The majority of these cases are among men who have sex with men (42%), followed by injection drug use (35%), men who have sex with men and inject drugs (10%), hemophilia/coagulation disorders (1%), and heterosexual contact with injecting drug users, sex with persons with hemophilia, sex with a transfusion recipient with HIV infection, or sex with an HIV-infected person with a risk that it is not specified (4%). An additional 1% of individuals have been infected through receiving a blood transfusion or blood components or through tissue transplant. A final 7% of individuals have an undetermined mode of infection.

Females make up approximately 20% of the AIDS cases in the United States. Of these cases, 46% were infected through drug use. Approximately 49% were infected through heterosexual contact with an injecting drug user, a bisexual male, a person with hemophilia or transfusion recipient with HIV infection, or an HIV-infected person whose risk was not specified; 3% of women were infected through blood transfusion, blood components, or tissue transplants; and approximately 2% were undetermined.

A total of 645,600 males had been diagnosed with AIDS as of 2001, with an additional 161,400 women in the United States. However, it is unknown how many individuals are infected with HIV but do not have AIDS. Among those who have AIDS, the CDC reports that 473,280 people were infected through unprotected sex, 204,000 were infected who shared needles, 53,000 were infected who had both unprotected sex and shared needles, 57,120 did not know how they were infected or did not report their risk or died before anybody could find out, 17,544 people got HIV from infected blood or blood products, 11,016 children were infected through their mothers, and 80 health care workers got infected through the blood or body fluids of patients.

#### HOW DO WE TREAT HIV INFECTION?

There is currently no cure for HIV disease. From March 1987 through early 2002, 16 anti-HIV drugs had received Food and Drug Administration approval, and two others had received expanded access approval. Unfortunately, these drugs are not curative,

and each has side effects. The most effective therapies are made up of combinations of drugs, often called triple drug therapy, or highly active antiretroviral treatment (HAART). Medications used to treat HIV are expensive, making them inaccessible to the large numbers of individuals infected with HIV in third world countries. The treatments require taking many pills across the course of each day.

Following HIV infection, there is a depletion of immune cells called CD4, or T4 cells. As the number of these cells is reduced, the immune system is unable to respond to various opportunistic infections. Individuals are then susceptible to protozoa (e.g., *Toxoplasma gondii*), which can lead to gastroenteritis or encephalitis; fungi (e.g., *Pneumocystis carinii*), which can lead to pneumonia or meningitis; bacteria (e.g., *Mycobacterium*), which cause tuberculosis; viruses (e.g., *Cytomegalovirus*), which cause hepatitis, fever, encephalitis, retinitis, pneumonia, colitis, and esophagitis; and cancers such as Kaposi's sarcoma.

Each of these diseases requires different treatments. For medical practitioners, this complexity of treatment means that many patients have problems with adherence to recommended treatments. Lack of adherence can lead to the patient developing drug-resistant strains of HIV. In addition to treatment complexity, lack of adherence can result from a number of sources including the potential for the development of cognitive problems. These problems arise from various infections of the central nervous system that may lead to memory problems, or in the worst-case full-blown dementia. In addition, HIV/AIDS is a stigmatizing illness and infected individuals may avoid disclosing their serostatus to family, friends, and coworkers. To avoid detection by others, doses may be missed. Finally, years of treatment sometimes result in infected persons tiring of the treatments and their associated side effects. This leads some patients to take "drug holidays," which may lead to drug resistance.

## HOW DO WE PREVENT THE SPREAD OF HIV?

To date there is no effective vaccine that prevents the acquisition of HIV. Aside from protection of our blood supply, all prevention takes the form of behavioral prevention. The majority of interventions have been focused on HIV-negative individuals who are at high risk of becoming infected (e.g., intravenous drug users, men who have sex with men). Needle exchange

programs have been shown to dramatically reduce the number of new infections among this segment of the population.

While there are many studies under way, efforts to change sexual behaviors have been less successful. Change in behavior is sometimes seen, but relapse to high-risk behavior is common. A smaller number of studies have focused on HIV-positive individuals who have unprotected sex with HIV-negative or unknown-status partners. It has been estimated that approximately 33% of HIV-positive individuals continue to have unprotected intercourse. The advantage of focusing on this group is that this represents a small number of individuals relative to the population as a whole, and such efforts should therefore be more cost-effective. Though small in number, results from interventions directed at this population have been promising. The issue of whether to target the general population versus specific groups is controversial, and while the distinction appears to be clear at first glance, the distinction is somewhat artificial. For example, sex with drug users may be a bridge between HIV-negative and -positive groups. In addition, it should be noted that sex between two HIV-positive individuals is also risky since infection with other sexually transmitted diseases (STDs) can have negative health consequences for an already immunocompromised individual. It should be noted that the CDC provides a Web site that promotes evidence-based interventions and provides materials for prevention efforts.

## WHERE DO WE CONDUCT PREVENTION EFFORTS?

In part the answer to this question depends on the population one wishes to target. HIV-infected individuals may be best reached in medical clinics where they seek care. STD clinics see groups of individuals who are by definition at high risk. In fact, having an STD increases the chances of becoming infected when exposed to the virus. To date little work has been conducted in these settings. Needle exchange programs have been conducted primarily in street outreach settings. However, there is increased interest in using pharmacies. However, this is not always practical since there are uneven laws, which are sometimes conflicting within a single jurisdiction. Conducting interventions in community-based organizations has the advantage of catering to specific populations in the neighborhoods where the population exists.

A number of areas of technology provide promise in HIV prevention efforts. For example, the World Wide Web can reach large numbers of individuals at a low cost and reaches individuals who might not otherwise be willing to participate in prevention programs. For example, men who have sex with men and live in rural communities are often unwilling to participate in such interventions. The Web provides an opportunity for this group to participate in an anonymous manner. Unfortunately, there are few published reports on the effectiveness of such interventions.

Adherence is another area in which technology may be helpful. Adherence may be improved through the use of watch timers, or automated computer programs that call patients with customized reminders to take their medications. Drug companies have taken advantage of these technologies in some areas to increase market share of costly drugs by providing these services at no cost to the patient.

Finally, technology may assist in assessments of risk behavior. Drug and sexual behaviors are private behaviors that may be illegal. Some data suggest that computerized questionnaires increase the accuracy of self-report. This may be due to decreased demand characteristics that individuals may feel when questioned by a human. For example, knowing he or she is participating in a sexual risk reduction intervention may lead a participant to minimize the number of high-risk encounters he or she has in some period. It should be noted that underreporting is but one problem of self-report. Problems also include overreporting, or in cases of high frequency of behaviors (e.g., number of sex partners for sex workers, or frequency of drug use) inaccurate reports may happen.

## WHAT ARE THE PSYCHOLOGICAL RESPONSES TO HIV INFECTION?

Psychological conditions associated with HIV illness can be categorized into adjustment disorders, anxiety and mood disorders, psychosis, and substance use disorders. In the context of HIV, the rates of adjustment disorders with depressed, anxious, or mixed features differ according to the population studied and appear to vary across key transition points. As might be expected, rates are highest in the days and weeks after an individual tests seropositive and may be elevated especially in workplace settings where testing is mandatory (e.g., military populations). In contrast, among individuals who have been voluntarily tested

and have known their serostatus on average for at least 1 year, rates of adjustment disorder are much lower even though these persons may be dealing with other HIV disease progression or treatment concerns. Crisis management has been shown to be effective in reducing the risks of adjustment disorder.

The rates of the major anxiety disorders in HIV—panic disorder, obsessive-compulsive disorder, and generalized anxiety disorder—appear to have lifetime and current prevalence within the range expected from community epidemiological studies and appear to be similar in prevalence across all disease stages. Their course is generally favorable and similar to that expected in non-HIV samples.

Individuals at risk for HIV infection appear to have elevated rates of major depression that preceded infection; after infection, their risk of major depression is at least in line with rates in populations of other chronic medical and neurological illness (e.g., stroke, multiple sclerosis, Alzheimer's disease, Huntington's disease, Parkinson's disease). Patients with primary bipolar disorder (manic-depressive) are believed to be at increased risk for HIV infection due to sexual sprees, poor judgment, and the disinhibiting effects of concurrent alcohol or drug use.

Prevalence estimates of psychotic disorders in HIV vary widely depending on study methodology. If one considers the prevalence of HIV infection for patients with schizophrenia being admitted to psychiatric hospitals in urban epicenters of the AIDS epidemic, perhaps 10% of schizophrenic persons are infected. When the psychotic disorder is due to HIV, large-scale surveys find low prevalence (< 0.5%).

Substance use disorders are important to detect for a number of reasons. For example, abuse or dependence can heighten likelihood of transmitting HIV by sharing of infected "works" by intravenous drug users (IDUs). In addition, non-IDU drug or alcohol abuse has been associated with higher-risk sexual behaviors. Finally, intoxication or withdrawal symptoms can complicate the neuropsychiatric presentation of the HIV-infected patient and complicate the identification and treatment of mood or psychotic disorders. Although some studies show higher current rates of substance use disorders among seropositive gay and bisexual individuals compared with those expected from community samples, others show roughly comparable or only slightly higher rates.

Another psychological topic that is important in HIV is suicide; there may be a 30-fold risk of committing

suicide among those with advanced disease compared with those who are seronegative matched for age and social position. Fatigue is also common in individuals with advanced disease. Decreased sleep quality, difficulty falling asleep, nighttime fragmented sleep, and early-morning awakenings seem to increase as immune function is compromised. Finally, pain has increasingly been recognized as a problem in HIV patients.

Almost any area of behavioral science has contributed to the body of literature on HIV. Not covered in this section were stress, social support, coping, and other closely allied areas of research. Nor did we review the compendium of work on psychoneuroimmunology as it relates to HIV progression. As this entry is being written, the number of new HIV infections continues to climb unabated. It is clear that the proximate cause of HIV infections resides in human behavior, most of it ordinary, some linked to psychopathology, but all of it potentially modifiable. The challenge to scientists and clinicians working in this area is to find efficacious ways to modify these behaviors in a cost-effective manner.

## AIDS AND HIV: ADHERENCE TO MEDICATIONS IN PERSONS WITH HIV INFECTION

---

### IMPORTANCE OF ADHERENCE TO ANTIRETROVIRAL THERAPY

Antiretroviral therapy is dramatically changing the course of HIV infection by influencing the medical management and health outcomes of persons with HIV infection (PWHIV). While this therapy has brought an increased sense of optimism and hope for PWHIV, it requires patients to be highly committed and strictly adhere to the therapeutic regimen. Adherence rates as high as 95% may be necessary (Paterson et al., 2000). In addition, there is a need for close monitoring of viral

load (HIV RNA) and CD4 T-cell counts to assess the effectiveness of the therapy (Andrews & Friedland, 2000). Investigators have demonstrated that lapses in antiretroviral adherence (missed doses) lower the likelihood of suppressing viremia below detectable levels (Paterson et al., 2000).

HIV is a retrovirus characterized by the presence of an enzyme, viral reverse transcriptase. This enzyme gives retroviruses the unique ability to synthesize DNA using an RNA template. The viral DNA is subsequently incorporated into the genome of the CD4 T-cell, the principal target for HIV, and replicates (Geleziunas & Greene, 1999). In the 1980s, researchers believed that HIV was a relatively silent virus and that HIV infection progressed slowly. Recent research demonstrates that HIV infection is a dynamic state in which billions of virions are produced and destroyed daily (Geleziunas & Greene, 1999).

Reverse transcriptase, the enzyme that copies the HIV genome, is error-prone, and makes, on average, one transcription error each time viral RNA is transcribed (Geleziunas & Greene, 1999). Consequently, the potential for viral mutation is high in PWHIV. Viral mutations along with subtherapeutic antiretroviral levels may result in the development of drug-resistant viruses and a worsening of symptoms (Geleziunas & Greene, 1999). In addition, adherence to antiretroviral therapy is associated with an increase in HIV RNA and the emergence of viral resistance.

### FACTORS ASSOCIATED WITH ADHERENCE TO ANTIRETROVIRAL THERAPY

Health care professionals and researchers are only beginning to understand the dynamic and complex nature of adherence to antiretroviral therapy. This understanding is necessary in order to match patient readiness with interventions designed to help patients adhere to the prescribed regimen. Studies published in the mid-1990s documented variable rates of adherence to antiretroviral drugs in PWHIV, ranging anywhere from 30% to greater than 90%. More recent studies continue to show a wide range (60-95%) of self-reported adherence. Researchers have demonstrated that PWHIV discontinue the use of antiretroviral medications on their own and report intentional missed doses and "drug holidays."

Identifying and understanding the factors that contribute to nonadherence is necessary in order to develop effective interventions that improve adherence

to antiretroviral therapy in PWHIV (Andrews & Friedland, 2000). Many of these factors occur simultaneously. Factors such as regimen complexity, number of prescribed drugs, dosing schedule, and side effects increase the likelihood of nonadherence to antiretroviral therapy. Other factors related to nonadherence include beliefs that treatment prolongs life, mood changes and greater depression, the need for psychiatric consultation, forgetting or taking less medication than prescribed, and substance abuse (Chesney, Morin, & Sherr, 2000; Paterson et al., 2000). Qualitative researchers have also examined the experience of medication taking among PWHIV. This work shows how side effects, dosing schedule, meal planning, and being away from home at the time a medication was to be taken contributed to nonadherence (Erlen & Mellors, 1999).

Race, symptoms, and stress have been shown to be associated with poorer adherence in PWHIV, whereas increased access and social support have been found to be associated with greater adherence. Other researchers have demonstrated that nonadherence is related to living a "marginal" lifestyle, one's social situation, and barriers such as being reminded of being HIV positive, not wanting others to know, and forgetting to ask providers questions (Catz, Kelly, Bogurt, Benotsch, & McAuliffe, 2000).

We are finding in our own work that perceived self-efficacy is significantly positively associated with adherence measured using both electronic event monitors and self-report. Also, physiological variables (symptoms, substance abuse, and perceived burden of regimen) and psychological variables (depression, social support, personality characteristics, and perceived stigma) are showing significant relationships with self-efficacy suggesting that self-efficacy may mediate these factors and adherence.

## INTERVENTION STUDIES TO IMPROVE ADHERENCE

Many people with chronic illnesses have difficulty following self-administered medication regimens, yet there are limited studies of interventions to improve adherence. One review article of adherence-promoting interventions tested in randomized controlled trials (RCTs) reported only 13 studies that used randomization, a control group, measure(s) of adherence, measure(s) of outcomes, and follow-up (Haynes, McKibbin, & Kanani, 1996). None of the

13 studies focused on PWHIV. The studies used various cognitive-behavioral interventions; half reported statistically significant improvement in adherence or treatment outcome among patients. Several studies had small samples, insufficient power to detect clinically meaningful effects, and short follow-up periods. More recently, McDonald, Garg, and Haynes (2002) reviewed adherence intervention RCTs (1967-2001). Of the 33 RCTs meeting inclusion criteria, only two studies had samples of PWHIV. Half of the 33 studies reported significant outcomes.

Psychoeducational interventions are demonstrating that they can help PWHIV achieve a self-reported adherence rate of 95% or higher. We are studying the effect of a multicomponent structured telephone-delivered intervention grounded in cognitive-behavioral therapy and targeted at various factors associated with adherence in PWHIV. This intervention is beginning to show a greater increase in adherence in the intervention group compared to the usual-care group. While treatment subjects become more adherent than control subjects, their adherence is not perfect.

Interventions that are used to improve adherence may need to be individualized because the person's needs change as his or her perspective about the disease or treatment changes. Published reports do not support one strategy consistently. Thus, multiple strategies from which providers can choose may be necessary to improve adherence. In addition, there is a need to consider the patient as partner and an active participant in the intervention. This approach is consistent with the literature that supports respect for patient autonomy as a key ethical value in understanding adherence. An individualized intervention has the potential to involve and support the patient throughout the intervention and address the multidimensional aspects of nonadherence: provider/health system-related, condition-related, therapy-related, and patient-related factors (Bartlett, 2002).

## HEALTH OUTCOMES

Given current knowledge, PWHIV will need to self-manage daily medication taking for the rest of their lives. Therefore, the patient's clinical response and quality of life are relevant health outcomes when assessing or intervening to improve adherence to antiretroviral therapy. Clinical response can be assessed through objective measures of viral load, CD4 T-cell counts, hospitalizations and emergency room visits

related to HIV infection, and increases in illness-related symptoms. On the other hand, quality of life is a subjective judgment on the part of the patient that can change over time. Improved therapies and increased length of survival have heightened the interest in examining quality of life in PWHIV.

Using assessments of viral load and CD4 T-cell counts, researchers are showing that low adherence and decreased therapeutic efficacy are related. When there are decreases in viral load, increases in CD4 T-cell counts, decreases in number of hospitalizations, and decreases in AIDS symptoms, health professionals can presume treatment efficacy due to patient adherence with treatment (Paterson et al., 2000).

Assessing quality of life provides a measure of how the lives of PWHIV are affected by adherence to antiretroviral therapy. As longevity increases, the satisfaction that PWHIV perceive from those aspects of life deemed to be of personal importance becomes even more significant. Some evidence exists that there is increased quality of life when patients adhere to their medication regimen (Erlen & Mellors, 1999). Because all aspects of quality of life are affected in PWHIV who are managing their adherence to a complex medication regimen, enabling PWHIV to adapt their lifestyle to a life that includes antiretroviral therapy and to adopt new health behaviors like adherence is very important.

#### IMPLICATIONS FOR RESEARCH AND CLINICAL PRACTICE

Antiretroviral drugs can be very effective therapy; however, the medications can be efficacious only if they are taken correctly. The regimen complexity and the various side effects increase the likelihood for PWHIV to be nonadherent. The documented evidence of nonadherence in PWHIV supports the need for well-designed intervention studies to promote and assess adherence to prescribed antiretroviral therapy.

Behavioral research is needed to address issues related to living with HIV. Since PWHIV will have to take these medications for the remainder of their lives, promoting adherence will require an intervention and maintenance program and periodic boosters to achieve positive health outcomes. Randomized clinical trials are needed to examine outcomes of behavior and the influence of self-efficacy on that behavior. Research needs to target the treatment of HIV infection and the management of adherence to long-term treatments.

From a clinical perspective, interventions need to use a multidisciplinary approach and be tailored to the patient's situation (Bartlett, 2002). Developing habits or using devices to remember to take medications, using support systems, and keeping medication diaries are strategies that can be incorporated into the patient's adherence plan. Comorbid conditions such as depression and substance abuse need to be addressed (Bartlett, 2002). While patient-related factors need to be considered, health professionals also need to attend to regimen-related, provider-related, and system-related factors that have the potential to affect adherence. The goals from both a research and a clinical practice perspective are to improve clinical outcomes and quality of life among PWHIV and to ultimately decrease health care costs.

## AIDS AND HIV: PREVENTION OF HIV INFECTION

---

Infection with HIV is the cause of AIDS. A person becomes infected with HIV when HIV-contaminated blood, semen, vaginal secretions, or breast milk enters his or her bloodstream. HIV transmission has occurred during blood transfusions, occupational and accidental exposure, maternal-child transmission, sharing of drug injection syringes or needles, and unprotected sexual intercourse. Although it is not possible to cure a person with AIDS, it is possible to prevent, or at least to reduce the likelihood of, HIV transmission through each of these routes.

### PROTECTING THE BLOOD SUPPLY

Early in the epidemic, before the virus was identified and procedures to test the blood supply were available, some people were infected by contaminated blood or blood products. Persons requiring frequent blood transfusions, such as those undergoing surgery or being treated for hemophilia, were most vulnerable to this mode of HIV transmission.

In 1985, it became possible to test blood for antibodies (molecules in the blood that are released to neutralize or destroy bacteria, viruses, or other microorganisms that invade the body) to HIV. Known as ELISA, or the enzyme-linked immunosorbent assay, this test identifies blood that may be infected with HIV.

Since 1985, efforts to prevent transmission of HIV through blood transfusions have relied on three strategies. First, all donated blood is now tested for HIV antibodies (as well as for hepatitis and syphilis). Second, potential blood donors with high-risk histories are not allowed to donate blood. Third, blood products that are infected with HIV are discarded.

Although there remains a very minute risk of receiving HIV-infected blood in a transfusion (the

antibody test used to detect HIV is not 100% perfect and blood donors who have been infected with HIV very recently may not develop antibodies for a few weeks), the likelihood of such transmission in the United States and most developed countries is now extremely low. Nucleic acid testing, a procedure that screens blood for HIV directly, promises to increase the safety of the blood supply even further in the coming years.

The blood supply outside of the United States and other developed countries remains a source of concern. Many developing countries cannot afford to screen their blood products and transmission via this mechanism continues.

### MINIMIZING OCCUPATIONAL AND ACCIDENTAL EXPOSURES TO HIV

Occupational exposures to contaminated blood and accidental needle-sticks among health care workers have led to some documented cases of HIV in the United States. The number of actual infections caused by this route is relatively small, but such infections have been reduced further in the United States through several prevention strategies.

One strategy involves the adoption of "universal precautions" procedures. Universal precautions begin with the assumption that all patients in health care settings could be infected with HIV; therefore, emergency medical personnel, health care workers, and others likely to come into contact with bodily fluids automatically protect themselves by wearing latex gloves and other protective coverings when caring for their patients. In addition, health care workers are required to dispose of uncapped needles and syringes in specially made, puncture-resistant containers. Universal precautions procedures also involve the incineration (or careful discarding in heavy-duty plastic bags) of medical waste, trash, and linens in hospitals and other health care settings.

Universal precautions procedures have also been used at athletic events to prevent accidental exposure to HIV from athletes who sustain a skin abrasion during a sporting event. Although the odds of HIV being transmitted from one athlete to another are believed to be exceedingly low (less than 1 in 1 million), at most sporting events athletes who sustain even a minor skin abrasion must leave the competition temporarily (to have the abrasion bandaged) so that no blood is accidentally transferred to other players.

A second strategy to reduce occupational or accidental transmission involves the use of postexposure prophylaxis, or PEP. This strategy, which typically involves completing a 1-month regimen of antiretroviral medications similar to those used to treat HIV infection, is used only when a person is exposed to a bodily fluid. In the case where an uninfected person is accidentally exposed to HIV, the use of PEP reduces the odds of HIV infection occurring by as much as 81%. Therefore, the Centers for Disease Control and Prevention now recommends PEP for health care workers who are accidentally exposed to HIV-infected body fluids.

As with blood screening, limited resources for medical supplies in many poorer countries make it difficult for these countries to implement such strategies to reduce accidental and occupational exposures.

## REDUCING MATERNAL-CHILD TRANSMISSION

Transmission of HIV from a mother to her infant child can occur through the placenta before birth and during delivery. The likelihood of perinatal transmission without medical intervention is estimated to be 25%. The risks of such transmission can be reduced to less than 10%, however, if a pregnant woman takes zidovudine (AZT) during pregnancy followed by brief treatment of the newborn infant. Such prevention strategies are used routinely now in the United States, and efforts are under way to make such treatments available worldwide; sadly, however, many women in developing countries still do not have access to such treatments.

Maternal-child transmission can also occur through breast-feeding after birth. Therefore, in the United States and other developed countries, HIV-infected mothers are discouraged from breast-feeding and advised to use commercially prepared infant formula instead. However, in countries where clean water is not available, and where infectious diseases and malnutrition cause significant infant mortality, the World Health Organization and other organizations recommend breast-feeding despite the possibility of HIV infection.

## PREVENTING HIV TRANSMISSION AMONG PEOPLE WHO USE INTRAVENOUS DRUGS

People who use intravenous drugs (e.g., heroin) can inadvertently transmit HIV to an uninfected person if they share their drug injection equipment or

“works” with one another. This is because needles and syringes often have small residual amounts of HIV-infected blood that can mix with the next users’ blood and lead to infection. If infected blood is present in a syringe that is shared, the likelihood of transmission is high. Indeed, in the United States, sharing of unsterilized drug injection syringes or needles accounted for 27% of the new infections in 2001.

Two prevention strategies have been used to help reduce the likelihood of HIV transmission among persons who use injection drugs. The first, a harm reduction approach, involves discouraging needle sharing through educational strategies and making clean needles available through needle exchange programs. Two studies completed in the United States found that HIV incidence was reduced by needle exchange programs; other studies in Canada and the Netherlands reported that needle exchange had no effect on HIV incidence (Carey & Venable, 2003). Despite this mixed evidence, most public health experts believe that needle exchange programs reduce needle sharing and may reduce HIV incidence; moreover, such programs also serve as an important link to drug treatment and other clinical services that can further reduce HIV risk.

A second strategy for risk reduction among people who inject drugs is to provide treatment for the drug abuse problem. Drug abuse treatment can reduce HIV risk both directly and indirectly. Direct effects can result from intervention components that target both risky sexual behavior and needle sharing. Indirect benefits result from improved decision making regarding partner selection and risk practices.

## REDUCING THE RISK OF SEXUAL TRANSMISSION OF HIV

In the United States and throughout the world, the most common method of HIV transmission involves unprotected vaginal or anal intercourse. Recent data from the United States indicate that 71% of the new infections in 2001 were the result of unprotected sexual intercourse. Epidemiological evidence suggests that transmission occurs most frequently through unprotected anal or vaginal intercourse but that transmission may also occur as a result of oral intercourse.

### Abstinence Programs

The most effective way to eliminate the sexual transmission of HIV would be to abstain from all

penetrative sexual activities. This prevention strategy has been recommended for adolescents who have not yet become sexually active or who are thought to be too young for sexually intimate relationships. A recent study by John Jemmott and his colleagues (Jemmott, Jemmott, & Fong, 1998) has provided evidence regarding the efficacy of an abstinence program. These authors evaluated the effects of an abstinence-oriented HIV prevention program by comparing it to a safer-sex program and a health promotion control group. The abstinence intervention stressed delaying intercourse, whereas the safer-sex intervention encouraged condom use if teens were sexually active. Both interventions took place during eight 1-hour meetings led by trained facilitators. The participants were 659 African American adolescents who were recruited from middle schools in low-income inner-city communities.

The efficacy of the interventions was determined by asking participants to complete confidential surveys regarding their sexual behavior 3, 6, and 12 months following the intervention. Self-report surveys were designed and administered carefully to optimize the participants' ability to recall their behavior and their willingness to disclose such sensitive material. Such self-reports, when carefully administered, provide data that are believed to be both reliable and valid (Weinhardt, Forsyth, Carey, Jaworski, & Durant, 1998).

The results the Jemmott et al. (1998) study indicated that, at the 3-month follow-up, adolescents in the abstinence intervention were less likely to report having sexual intercourse than were control group participants; however, this effect weakened at the subsequent follow-up evaluations. As expected, students in the safer-sex intervention reported higher frequency of condom use at all follow-ups. Among adolescents who reported sexual experience at baseline, the safer-sex intervention group reported less sexual intercourse at 6- and 12-month follow-ups than did the control and abstinence intervention, and less unprotected intercourse at all follow-ups than did the control group. The results indicate that both abstinence and safer-sex interventions reduced HIV sexual risk behaviors but that safer-sex interventions have longer-lasting effects and are more effective with sexually experienced adolescents.

### **Sexual Risk Reduction Programs**

For adults and adolescents who remain sexually active, prevention efforts tend to encourage one or

more risk reduction strategies. One strategy involves mutual monogamy with an uninfected partner. This approach prevents HIV only if two partners (a) get tested for HIV prior to having sexual contact, (b) test negative, and (c) agree to have no other sexual partners. If such conditions are met, then HIV infection as a result of unprotected sex within the relationship is very unlikely. (There remains a very small chance that the HIV test was inaccurate or that the results did not reflect a very recent infection with HIV because HIV antibodies may not develop for a few weeks after infection.)

A second strategy involves "negotiated safety." In such a relationship, partners typically agree to steps (a) and (b) but not (c) above. Instead, they agree to use a condom if they have sexual relationships outside of their primary relationship.

A third strategy involves reducing the number of sexual partners, or shifting from higher-risk to lower-risk sexual activities (e.g., from vaginal sex to oral sex). These strategies reduce risk somewhat but still leave a person quite vulnerable to infection should they have a sexual relationship with an infected partner.

A fourth risk reduction strategy involves condom use. If used consistently and correctly with all partners, latex condoms significantly reduce the risk of HIV transmission.

Collectively, these risk reduction strategies are sometimes referred to as "safer sex," a term that is intended to convey the idea that any sexual contact involves some risk, and none of these strategies reduces risk completely. However, such practices do reduce the risk considerably and are "safer" than high-risk practices involving unprotected sex with multiple partners whose HIV status is unknown. Overall, the level of protection provided by these strategies depends on the circumstances, partner characteristics, and actual behaviors.

There is now a large literature devoted to evaluating the efficacy of such safer-sex strategies. Risk reduction programs have been evaluated in a wide range of settings, including clinics that provide services for sexually transmitted diseases (STDs), family planning, and other sexual health needs; primary, secondary, and higher educational environments; prisons; military bases; and a range of community-based settings. Programs have been tailored to address the unique needs of men who have sex with men, heterosexual women, adolescents, alcohol and drug users, persons living with mental illness, and other populations.

Although most research has been conducted in the United States, there is now a substantial amount of research that has been conducted throughout the world.

Two large studies in the United States demonstrate that well-designed intervention programs can lead to reduced risk behavior and lowered incidence of new STDs. The National Institute of Mental Health (1998) Multisite Study investigated the efficacy of a group-based intervention with 3,706 high-risk men and women who were recruited from 37 medical clinics across the United States. The intervention evaluated was based on Jeffrey Kelly's (1995) skills training approach and was administered to small groups during seven sessions. Participants who learned self-management and condom use skills, as well as interpersonal skills and education about HIV, reported fewer unprotected sexual acts, had higher levels of condom use, and were more likely to use condoms consistently over a 12-month follow-up period. In addition, those men who were recruited from an STD clinic also had a gonorrhea incidence rate that was one half that of the control group.

A second study, sponsored by the Centers for Disease Control and Prevention, investigated an individualized intervention and was conducted in publicly funded STD clinics (Kamb et al., 1998). This trial enrolled men and women once they agreed to have an HIV test, and tested two interventions (a four-session counseling program lasting 200 minutes, and a two-session counseling program lasting 40 minutes), and compared them both to a standard care (educational) program. Compared with participants in the educational program, participants in both counseling interventions reported more condom use at 3 and 6 months postintervention. After 6 months, 30% fewer participants in both counseling interventions had new STDs, and after 12 months, 20% fewer participants had new STDs. Benefits were similar for men and women.

Scholarly reviews of many studies consistently identify several characteristics of effective HIV prevention programs to reduce the risk of sexual transmission. First, such programs have been developed from theoretical models that identify multiple determinants of sexual risk behavior. The most prominent models are derived from Albert Bandura's (1994) social-cognitive theory, and recognize the influence of intrapersonal, interpersonal, dyadic, and other environmental factors. Second, successful interventions often have a strong behavioral skills component, which helps

program recipients to strengthen self-management, condom use, and interpersonal negotiation skills while simultaneously becoming better informed about HIV transmission and prevention, and more aware of personal vulnerability to HIV infection. Conversely, it is recognized that prevention programs that only provide HIV education tend to be a much less effective method for reducing risk behavior (Johnson, Carey, Marsh, Levin, & Scott-Sheldon, 2003).

Evaluation of existing prevention programs for reduction of sexual transmission has also identified some limitations. One concern involves the dissemination of empirically demonstrated interventions to large populations and to community-based providers. An innovative approach to dissemination based on social diffusion theory involves recruiting and training "popular opinion leaders" who then attempt to influence friends and associates in their social networks. This approach has shown initial promise and may be an efficient method of disseminating risk reduction strategies across a large population.

A second concern involves the durability or sustainability of risk reduction. Most research studies follow participants for 1 year or less, and often reveal that the prevention effects tend to decrease over time. Because the need for behavior change is lifelong, such findings suggest the need to develop more effective methods to extend the benefits of risk reduction programs. The use of media messages to provide support and encouragement for people who have reduced their risk is one approach being investigated by public health researchers.

#### *Risk Reduction for HIV-Infected Persons*

Most primary prevention programs target people who are at risk for, but not yet infected with, HIV. An alternative and potentially more efficient approach to preventing new infections is to implement behavior change interventions for people who are already infected with HIV. Although many persons living with HIV refrain from risky sexual behaviors, studies of gay men, injection drug users, and patients recruited through HIV clinics indicate that at least 30% of persons living with HIV engage in risky sexual behaviors.

Sexual risk behavior among persons living with HIV is important for at least three reasons. First, such behavior threatens the health of people who are not yet infected. Second, HIV-infected patients who engage in risky sexual behavior, especially those who

develop multiple drug resistances to HIV combination therapies, may then transmit drug-resistant HIV strains to HIV-positive sexual partners; such “reinfection” or “superinfection” with a treatment-resistant strain of HIV is believed to contribute to poor treatment outcomes. Third, HIV-positive individuals who engage in unprotected sex may become infected with other STDs. The presence of other STDs increases HIV infectivity, making it more likely that HIV will be transmitted to uninfected partners.

Paradoxically, the availability of improved HIV treatments has eroded commitment to safer sex due to the belief that AIDS is no longer the dire health threat it had been. Such concerns may be particularly relevant to persons living with HIV because they have had more direct experience with the newer therapies. In a study involving HIV-positive and HIV-negative gay men (Venable, Ostrow, McKirnan, Taywaditap, & Hope, 2000), more than a quarter of respondents endorsed agreement with items reflecting reduced concern about HIV due to new treatments. More important in terms of prevention implications, reduced HIV concern was associated most strongly with sexual risk taking (unprotected anal sex) among HIV-positive participants, suggesting that the availability of combination treatments has had a greater impact on the sexual behavior of men living with HIV.

HIV risk reduction interventions involving persons living with HIV have been limited. Research on HIV counseling and testing suggests that posttest counseling promotes short-term reductions in HIV risk behavior among newly infected men and women (Weinhardt, Carey, Johnson, & Bickham, 1999), but other research reveals continued high-risk behavior among persons with HIV. Taken together, these findings suggest that posttest counseling is not enough. One study tested the effectiveness of providing risk reduction information and emotional support with 271 HIV-positive men and women (Cleary et al., 1995). Results indicated a general decline in sexual risk taking among all participants, but no clear advantage of the risk reduction intervention over the gains observed among control patients who were randomized to a community referral source.

One of the few studies that has evaluated a risk reduction intervention for HIV-positive adults was reported by Seth Kalichman and his colleagues (Kalichman et al., 2001). They compared a five-session, group-based intervention to a contact-matched support group with a sample of 332 men and women

living with HIV. The intervention included skills training (a) to cope with high-risk sexual situations, (b) to disclose HIV serostatus to partners, and (c) to negotiate condom use with sexual partners. The results showed a reduction in risk behavior was observed among HIV-positive participants receiving the intervention to reduce sexual risk behavior, whereas no such reduction was observed in the control group.

Work designed to assist people with emotional adjustment and coping with HIV infection has also demonstrated some risk reduction benefits. For example, Thomas Coates and his colleagues (Coates, McKusick, Kuno, & Stites, 1989) conducted a stress management program for HIV-positive men in San Francisco that included relaxation training, systematic desensitization, physical exercise, and self-management training. Although risk reduction was not a primary goal of the intervention, participation in the program was associated with a reduction in participants' number of partners. Jeffrey Kelly and colleagues (Kelly et al., 1993) reported similar effects using a support group for depressed HIV-positive men. Taken together, these findings suggest that HIV risk reduction counseling is most beneficial if it is included within a broader array of psychosocial services for persons living with HIV.

## HIV VACCINE

There are no vaccines that can prevent HIV transmission. Research investigating candidate vaccines is under way but is expected to require a decade or more to complete.

## AIDS AND HIV: STRESS

---

The Centers for Disease Control and Prevention estimates that 850,000 to 950,000 U.S. residents are living with HIV, with about 40,000 new HIV infections each year. HIV is the fifth leading cause of death among those ages 25-44; it is the leading cause of death among African American males in this same age range. The development of potent combination antiretroviral therapies for HIV has lengthened life expectancy for HIV-infected persons in the United States. A person with HIV can live for many years without getting AIDS, that is, the occurrence of severe medical symptoms and/or decline in the immune system's helper cells. Despite advances in HIV treatment, there is wide variability in the length of time before a person dies, develops clinical symptoms, or has a weakening in their immune system. Evidence has been mounting that chronic stress may have an adverse effect on the immune system of those infected with HIV, leading to faster disease progression and death.

The Coping in Health and Illness Project (CHIP), conducted by researchers at the University of North

Carolina at Chapel Hill, has reported some of the most consistent and compelling data on the deleterious effects of stressful life events and difficulties in HIV infection. CHIP is a 9-year longitudinal study following 96 HIV-infected gay men who began the study without HIV-related symptoms or HIV medications. To measure stress, the CHIP study uses interviewer-based ratings assessing the severity of patients' stressful life events and difficulties taking into account the circumstances surrounding events (e.g., financial impact, life threat, personal involvement). The objective threat rating is made independently from the subject's rating, to reduce the possibility that worsening disease might lead to poor coping and thus higher stress scores. The measure also excludes stresses that could have resulted from disease progression (e.g., retirement due to HIV worsening). This methodology is one way to avoid the chicken-egg issue of whether stress leads to worsening disease or whether those with declining health rate their stressful events as more unpleasant.

Leserman, Evans, and colleagues from the CHIP study found that men with more stresses during a 9-year period had faster progression to AIDS and faster development of serious HIV-related illnesses (such as pneumocystis pneumonia, Kaposi's sarcoma). Men who had a severe stress at every visit had about twice the risk of progressing compared to men who never had a severe stress. The AIDS progression rate at the end of 8 years for those above average in stress was 74% versus 40% for those below average. The investigators reported similar findings during earlier time periods of the study. Their findings were not explained by differences among patients on such variables as age, race, education, number of HIV medications, or entry levels of helper cells or HIV viral load (amount of virus in the blood).

Another approach to establishing a causal relationship between stress and disease progression has been to study patients who have experienced a major stressor, such as death of a loved one. These types of stressors can clearly be documented before changes in disease status, making the direction of such a relationship less ambiguous (e.g., changes in disease status are more likely to be a result of a major stressor than vice versa). In studying HIV-infected gay men, Kemeny and researchers at the University of California, San Diego, reported that the stress of bereavement prior to their study (having a close friend or lover who died of AIDS) was associated with more rapid decline in helper cell count during a 3- to 4-year period. These findings were

not explained by differences in health habits, HIV medication use, or age; however, bereavement was not related to faster development of AIDS medical symptoms or mortality. In a later study of men during 2- to 3-year follow-up, these researchers showed that those who found meaning in bereavement had less rapid decline in helper cell levels and lower rates of mortality due to AIDS. In studying another stress, being notified of being HIV positive, researchers at the University of Miami found that men with more distress at notification had a greater chance of developing HIV-related clinical symptoms 2 years later.

In one of the few studies of African American HIV-infected women, investigators found that lifetime exposure to traumatic events (e.g., death of child, assault, rape) was associated with greater immune compromise, especially among patients with a psychiatric disorder related to the trauma (e.g., posttraumatic stress disorder). During a 1-year study of 618 HIV-infected children and adolescents, having two or more stressful life events (e.g., death, loss or major illness of family member) was associated with an almost three-fold increased risk of immune suppression (decline in helper cells). These findings were not accounted for by baseline helper cells or demographic variables.

Capitanio and colleagues at the University of California, Davis, have examined the effects of social stress (e.g., unstable social group) on survival of male rhesus monkeys infected with the simian version of HIV (SIV). The animals subjected to an unstable social group (high stress) survived a significantly shorter time (169 days) compared to those in the stable group (low stress). Furthermore, animals that received threats from other animals had higher SIV viral load (more virus in their bloodstream) compared to those not receiving threats, regardless of whether they were in a stable or unstable social group.

Although the research described above gives compelling evidence for a relationship between stress and HIV disease progression, negative findings were reported in several studies using questionnaires to measure stress and using a study design with a short follow-up period. In addition, it is difficult to establish a causal relationship between stress and disease outcome, given that some underlying cause may account for this relationship. Stressful events and trauma, however, appear to have a negative impact on HIV disease progression, especially in studies done over longer time periods and those examining actual stressors (e.g., bereavement) or using interviewer-based ratings of stress.

There is limited evidence that cortisol, a hormone associated with stress, also has a negative impact on HIV infection. Several research groups have reported an association of higher levels of cortisol with poorer immune response, lower helper counts, and faster progression to AIDS and to mortality. These findings remain controversial, and more research is needed to determine whether cortisol might be the link to explain why stress may have a deleterious effect on HIV disease status.

If stressful events are related to HIV disease progression, what is the evidence that interventions aimed at improving coping and reducing distress may improve immunity and ultimately the health status of HIV-infected persons? Although there have been only a few studies addressing this question, researchers at the University of Miami report that both cognitive-behavioral stress management and a bereavement support group appear to improve psychological health and the immune response of persons infected with HIV. These studies have included relatively short follow-up periods, and it remains a question of whether these interventions will have long-term beneficial effects. The available studies suggest that psychological treatments may ameliorate the negative effects of stress, and as such have a salutary impact on the course of HIV, at least in the short run.

To conclude, there is substantial evidence that stress may affect disease progression in those infected with HIV. It must be noted, however, that the majority of studies on stress and HIV infection have been conducted on men, primarily before the advent of protease inhibitors, the most effective HIV medication. Therefore, the findings from the reviewed studies may not apply to women or to those currently taking potent combination HIV medications. If studies continue to show that stress alters the course of HIV infection, it will be important for HIV researchers and clinicians to consider stress management interventions, in addition to medical therapies, to treat this devastating illness.

## ALAMEDA COUNTY STUDY

---

The Alameda County Study is one of the major research projects that evaluate the effects of health habits in a free-living population. In public health terms, it is a study of social epidemiology. The study originally identified 8,300 adults who lived in 4,735 households. Eighty-six percent of the eligible adults completed questionnaires, and these 6,928 individuals have been followed by the investigators for 25 years.

The study began in 1965, and by the mid-1970s, a variety of interesting findings began to emerge. For example, a series of important analyses demonstrated that health habits were a major predictor of survival for the residents of this urban California community. The specific predictors of surviving (not dying early) included not smoking cigarettes, using alcohol in moderation, being average weight, moderate leisure time physical activity, and obtaining 7 to 9 hours of sleep each night. In some of the analyses, the investigators simply counted the number of good health habits the participants engaged in. They found systematic relationships between the number of these activities and both morbidity (illness) and mortality (early death). For example, those who engaged in none of these practices were 3.11 times more likely to die of heart disease than those who engaged in five of the activities.

The second wave of the Alameda County Study began in 1974. Data were collected from 4,864 of the

original respondents. The study later followed the same individuals in 1994 and 1995. This most recent follow-up provides information on 2,729 of the respondents who had participated in the 1965 and 1994 surveys. The focus on the third follow-up was on health behaviors such as alcohol consumption, smoking, and social activity. The study also provided detailed evaluations on conditions such as diabetes, osteoporosis, hormone replacement, and mental illness. The Alameda County Study, in contrast to many epidemiological studies, focuses on social activities. For example, it included sections on self-care, use of free time, and involvement in social, recreational, and religious activities.

The Alameda County Study also broke new ground by demonstrating the relationship between social support and health outcomes. Those who were more “socially connected” had significantly greater chances of survival than those who were less connected. Among the many important findings from the Alameda County Study is the observation that participation in religious activities was associated with positive health outcomes. However, the relationship between church attendance and health outcomes might be challenged because those who usually attend religious activities may consume less alcohol, have healthier diets, smoke less, or have fewer sexual partners. To investigate this issue, recent publications from the Alameda County Study have provided statistical controls for at least eight other explanatory variables. Even with these controls, there was a statistical benefit of attendance of religious activities. The finding was stronger for women than it was for men.

In summary, the Alameda County Study has provided a significant amount of information on the relationship between behavioral patterns and health outcomes. The study remains active, and we expect continuing important contributions to the literature.

## ALCOHOL ABUSE AND DEPENDENCE

---

In U.S. general population surveys, approximately 70% of men and 60% of women report drinking on at least one occasion during the previous year. The

majority of drinkers consume light to moderate amounts of alcohol (typically defined as no more than one drink per day for a woman and two drinks per day for a man) and experience few, if any, negative health effects of drinking alcohol. Those negative effects that do occur, such as cognitive impairment and decreased motor skills/coordination, tend to be short term, usually resolving themselves as soon as alcohol is metabolized and removed from the body. Recent research suggests that moderate drinkers may even experience long-term cardiovascular benefits of alcohol.

Among those who have ever consumed alcohol (approximately 92% of the adult population), prevalence surveys suggest that up to 14% eventually develop alcohol dependence. At the higher levels of use that characterize alcohol abuse and dependence, alcohol consumption is related to negative health effects as well as increases in other high-risk behaviors such as smoking and violence. At these higher levels of intake, alcohol can have significant negative effects on health, either directly through the pharmacological and toxic effects of ingesting excessive amounts of ethanol or indirectly through their interaction with other problem and high-risk behaviors.

### WHAT IS ALCOHOL ABUSE?

Alcohol abuse involves alcohol intake that causes problems and is maladaptive. In the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* of the American Psychiatric Association, alcohol abuse is said to occur when the individual experiences impairment or distress related to any one of the following symptoms within a 12-month period: excessive drinking that leads to repeated failures to fulfill responsibilities at work, school, or home; physically hazardous drinking (e.g., while driving); repeated legal problems; and continuing to drink despite alcohol-related social or interpersonal problems.

### WHAT IS ALCOHOL DEPENDENCE?

The *DSM-IV* describes alcohol dependence as involving maladaptively high alcohol intake that produces impairment or distress. Persons diagnosed as alcohol dependent experience at least *three* of the following symptoms within a 12-month period: tolerance (e.g., the need to increase alcohol intake to achieve the desired effects); withdrawal symptoms (e.g., shakiness,

seizures) when alcohol is not available; impairment in the ability to control alcohol intake (e.g., desire for alcohol and lack of success cutting down on alcohol intake); neglect of important activities such as work; large amounts of time spent on alcohol-related activities; and continuing to drink even though experiencing recurring alcohol-related physical and psychological problems.

Although the diagnostic criteria portray alcohol abuse and dependence as categorical phenomena, it is possible to view alcohol consumption and alcohol problems as involving a continuum from no use or problems to heavy drinking and severe problems. Along this continuum there is much heterogeneity in patterns of use and the nature and extent of alcohol problems. Moreover, patterns of use can change over time. Some individuals report a linear progression from social drinking to alcohol abuse followed by dependence. Others exhibit stable patterns of either problematic or nonproblematic alcohol use over time, or move back and forth among patterns (e.g., alternating between long periods of heavy and light drinking patterns).

#### WHAT CAUSES ALCOHOL ABUSE AND DEPENDENCE?

Alcohol abuse and dependence are complex behavioral problems caused by the interaction among a multitude of biological, psychological, and social factors. Individuals vary in the nature and extent to which each of these sets of factors contributes to the development and maintenance of their alcohol problems.

Chief among the *biological factors* are gender and genetics. Women's bodies typically contain less water per unit of body weight than do men. Because alcohol is a water-soluble substance, this physiological difference results in higher peak blood levels of alcohol in women than men per body-weight-adjusted dose. Men and women also differ in their metabolism of alcohol. It appears that these biological differences contribute to women being more vulnerable than men to the potential negative health effects of alcohol consumption. Biological differences, combined with social norms related to women's drinking, generally produce a pattern in which more men than women drink alcohol, and the amount of alcohol consumed by men typically exceeds that consumed by women. Research suggests also that genetic/hereditary factors play a role in the development of alcohol abuse and

dependence. However, the genetic contribution to alcohol-related problems is complex, the specific genes or constellation of genes that contribute to alcohol abuse and dependence have not been identified, and the behavioral implications of identifying the genes that contribute to having problems with alcohol are not clear.

Among *psychological factors*, researchers have suggested that learning from the social environment (i.e., social learning) can play a role in the development of drinking behavior. This occurs both as a function of direct experiences of the positive rewards of drinking (e.g., social acceptance, change in consciousness) and indirect experiences (e.g., seeing alcohol's effects on others). The combination of "risky" temperaments (which include high activity, low attention span, and high emotionality) and difficult family environments has been associated with a range of problem behaviors (e.g., delinquency, aggression) that include early involvement with alcohol and later alcohol abuse and problems. However, the popular lay notion that an "addictive personality" is the cause of alcohol abuse and dependence has not been empirically substantiated. Psychiatric and psychological problems such as schizophrenia, depression, and anxiety disorders are positively associated with alcohol problems. This association has been seen as supporting the notion that some people use alcohol and other drugs to "self-medicate," that is, to relieve negative psychological symptoms so that they feel better.

*Social/environmental factors* that may contribute to alcohol abuse and dependence include drinking norms and practices associated with one's family of origin, ethnic/cultural group affiliation, and religious orientation. Thus, ethnic groups, religions, and families that promote norms for abstinence or light drinking are less likely to produce persons who meet criteria for alcohol abuse and dependence. Similarly, social and economic policies that influence the availability of and access to alcohol (e.g., legal drinking age, zoning of alcohol outlets, taxes on alcohol) also influence patterns of alcohol use and the development of alcohol abuse and alcohol dependence. For example, in the United States, alcohol prohibition during the 1920s and early 1930s produced reductions in the rates of alcohol abuse and dependence. With the repeal of prohibition, rates of alcohol abuse and dependence increased.

Demographic characteristics such as gender, age, and ethnicity are related to a variety of factors ranging

from occupations and attitudes to socioeconomic status (SES). These factors independently and interactively influence drinking patterns and rates of alcohol abuse and dependence. When we consider the role of demographic characteristics in drinking behavior, prevalence data tell us that men drink more (in frequency and amount) than women and that, relative to women, a larger percentage of men are diagnosed as either abusing alcohol or dependent on alcohol. For both men and women, alcohol intake is highest in young adulthood (ages 18 to 25), with gradual decreases as persons become older. Nevertheless, there is a growing concern about drinking problems among the elderly, particularly given the relatively higher prevalence of alcohol abuse and dependence among the large baby boomer generation, which is aging and becoming elderly.

Alcohol abuse and alcohol dependence can be found in all ethnic groups. Although there is much heterogeneity of drinking patterns within ethnic groups (including variations related to age, gender, and SES), prevalence data suggest that rates of alcohol abuse and dependence also vary with ethnicity. For example, a combination of biological, psychological, social/historical, and environmental factors have contributed to higher rates of alcohol abuse and dependence among members of certain Native American groups, while Asian Americans report lower than average rates of alcohol abuse and dependence.

## SHORT-TERM EFFECTS

Alcohol use can have a number of effects on health through its short-term, or acute, effects on behavior. In particular, alcohol's effects on cognitive-motor functioning and decision making increase risk for injury and illness.

### Cognitive and Motor Functioning

Alcohol's acute effects on cognitive functioning are complex and are dependent on the nature of the task, the dose of alcohol consumed, and the time since ingestion. Generally, alcohol-related impairment increases as blood alcohol concentration increases and decreases as alcohol is metabolized and removed from the body. However, the effects at a given blood alcohol concentration can differ depending on whether the concentration is rising or falling (the "biphasic effect" of alcohol). For example, a moderate dose of alcohol

may produce behavioral stimulation and euphoria initially, followed quickly by a sedative effect.

Many behavioral effects of acute alcohol use are thought to be mediated by alcohol's impact on cognitive processing and motor function. For instance, alcohol-induced slowing of reaction times and impairment in ability to perform cognitive tasks (e.g., dividing attention between multiple stimuli) contribute to the increased risk of accidents that accompanies driving after drinking. Under certain conditions, alcohol's short-term effects on cognitive processing may contribute to an increased likelihood of violent behavior, accidents, unintended pregnancy, and sexually transmitted disease infection.

## Violence

Alcohol is commonly cited as a cause of violence. Whether violence takes the form of fights at a bar or football game, physical abuse of a spouse, or even suicide, it is often the case that participants in violence have been drinking. Indeed, it has been estimated that roughly 50% of perpetrators (and victims) of violence have been using alcohol prior to the violent incident. An association between alcohol and violence occurs among varying demographic subgroups, for different types of violence, and even across countries, although the strength of the association varies widely. Research suggests also that the amount of alcohol consumed is related to the severity of the violence.

Despite popular beliefs that alcohol abuse is a cause of violence, the relationship between the two is rather complex and is not unidirectional. Some evidence suggests that alcohol causes violence in certain situations by affecting the way we process information in the brain. For example, according to the "alcohol myopia" theory, alcohol narrows the focus of cognitive processing so that immediate cues and sensations enter awareness, but peripheral cues, including those that inhibit socially inappropriate behavior (such as aggression), do not. Thus, an intoxicated man in a bar may feel angry and start a fight after being accidentally pushed, not thinking that to do so might get him hurt or arrested. An implication of this theory is that alcohol will have its greatest effect on behavior that is subject both to strongly instigating cues (e.g., being shoved) and to strongly inhibiting cues (e.g., fear of being arrested). Without instigation, the behavior is unlikely even if alcohol has been consumed. Conversely, without inhibiting cues, the behavior will likely occur even in the absence of alcohol use.

Other evidence raises the possibility that aggression after drinking sometimes happens because the individual expects alcohol to cause violence and acts in a manner consistent with expectations, like a self-fulfilling prophecy. Drinking and aggression may be linked also because both tend to occur in similar situations, or because personality characteristics that foster heavy drinking also reflect an increased tendency toward violence. The most likely conclusion may be that all of these factors interact to produce the commonly observed link between alcohol use and violence.

### **Injuries**

Beyond its relationship to violence, alcohol use is associated with unintentional injuries stemming from automobile and boating accidents, falls, fires, and similar occurrences. The increased risk of injury likely results from a combination of factors, including impaired cognitive and motor functioning as well as increased risk-taking behavior when drinking. Alcohol also leads to more severe effects when injuries do occur, because of its effect on the heart and circulatory system. As with violence, some types of unintentional injury may tend to co-occur with alcohol use because both drinking and risky behavior are more likely in certain environments and settings (e.g., bars), or among certain demographic subgroups (e.g., young adults). A pattern of binge drinking, in which a large amount of alcohol is consumed during a single drinking occasion, is particularly associated with increased risk for injury, due to the high blood alcohol concentrations reached.

### **Unintended Pregnancy and Infection With Sexually Transmitted Disease**

Risky sexual behavior includes not using birth control, not using disease-preventive measures such as condoms, and being less selective regarding choice of sexual partners. Such behavior often is believed to result from excessive drinking. However, the evidence that alcohol can increase sexual risk taking is inconsistent. The strongest evidence for an effect on condom use, for instance, comes from research with adolescents. Among adults, there is little clear evidence that alcohol use and sexual risk behavior are associated. It may be that among adolescents, alcohol's effects on cognitive processes can more easily disrupt patterns of self-protective behavior such as condom and/or birth

control use, because such patterns are less well established and less habitual than among adults.

### **LONG-TERM EFFECTS**

Over years of use, alcohol's direct and indirect toxic effects in the body can lead to serious negative health consequences. These outcomes are particularly likely with sustained heavy drinking or a pattern of regular (e.g., weekly) binge drinking. These long-term effects occur in several bodily systems, including organs such as the liver that are directly involved with metabolizing alcohol as well as the immune and cardiovascular systems.

#### **Immune Function**

Evidence suggests that alcohol abuse has a complex, negative impact on the immune system, causing both immunodeficiency and autoimmune reactions. For instance, alcohol-dependent individuals often have greatly increased blood levels of immunoglobulins, which are antibodies produced by white blood cells called B-lymphocytes (or B-cells). Although different classes of immunoglobulin have different roles in immune response, higher levels of a given antibody are typically associated with a specific immunity, like that resulting from a vaccination. However, alcohol dependence accompanied by highly elevated levels of immunoglobulin often is associated with immunodeficiency.

Heavy alcohol consumption has direct effects on immune function as well as indirect effects stemming from organ damage (e.g., liver disease). Immune system components affected include T-cells and B-cells, neutrophils and monocytes (from the class of white blood cells called phagocytes), and cytokines (protein molecules secreted by immune system cells). Alcohol's effects on the immune system may explain at least partially why individuals who abuse alcohol are at greater risk for diseases related to immunodeficiency, such as pneumonia, tuberculosis, HIV infection (which eventually leads to AIDS), and hepatitis B and C, as well as diseases related to autoimmunity, such as alcoholic hepatitis, alcoholic cirrhosis, and kidney disease.

#### **Cardiovascular Disease**

Consumption of large amounts of alcohol has acute and chronic effects on the heart and related systems.

Alcohol's effects on cardiovascular disease (CVD) are complex. There is mounting evidence that moderate drinkers exhibit lower levels of CVD-related mortality, suggesting that alcohol has a protective function that is possibly related to increasing high-density lipoprotein (HDL) levels that help to reduce the buildup of cholesterol in the blood vessels. Even so, CVD-related mortality is high among heavy drinkers and binge drinkers. Thus, the *pattern* (i.e., amount and frequency) in which alcohol is consumed along with the overall history of alcohol consumption plays a causal role in CVD.

Acute exposure to large doses of alcohol, as occurs with binge drinking, can precipitate heart attacks or sudden death, particularly among those with a long-term history of alcohol abuse. Evidence from human and animal research suggests four possible physiological mechanisms for producing binge-drinking-related sudden death due to CVD. These include the effects of binge drinking on (1) lipids—binge drinking is associated with increases in low-density lipoproteins (LDLs) and other lipid changes; (2) clotting—alcohol inhibits the aggregation of platelets, thereby making it more difficult for blood to clot; (3) arrhythmia—binge drinking reduces the threshold for ventricular fibrillation and/or scars the myocardium; and (4) hypertension—binge drinking increases blood pressure, particularly systolic pressure. These cardiovascular effects of binge drinking can occur within 12 to 24 hours of heavy alcohol intake. Chronic and more insidious effects of alcohol include cardiomyopathy, which involves enlargement of the heart and loss of the heart muscle's ability to contract. Cardiomyopathy is seen after 10 years or more of excessive drinking and so usually becomes evident beyond the age of 30 years.

## Cancer

Population-based epidemiological research has indicated that as the dose of alcohol increases, so too does risk for developing certain cancers. The heavy drinking that characterizes alcohol abuse and dependence is most strongly related to cancers of the upper digestive system (i.e., the mouth, pharynx, and esophagus). Links between heavy alcohol use and increases in the risk for breast, liver, and colorectal cancers have been suggested, but the research findings are inconsistent and the interpretation of the findings controversial. The mechanisms through which alcohol

contributes to the development of cancers are not well understood. Alcohol may cause cancers directly, through the effects of metabolism by-products such as acetaldehyde, which stimulates bodily reactions that can cause tissue damage. Alcohol also may work indirectly, through its interactions with certain enzymes that increase the toxicity of some carcinogens. For example, alcohol has been found to enhance tobacco's ability to stimulate the growth of tumors in rats. Compared to abstainers, humans who both drink and smoke are at 35 times greater risk for developing cancers of the upper digestive system.

## Liver Disease

Most of the alcohol that an individual consumes is metabolized by the liver. Thus, the liver is susceptible to damage from toxic metabolites such as acetaldehyde, a by-product of alcohol metabolism, which stimulates bodily reactions that can cause tissue damage. Those who meet diagnostic criteria for alcohol abuse and alcohol dependence are at high risk for liver-related illnesses. For example, up to one third of alcohol abusers develop alcoholic hepatitis, and up to one fifth of alcohol abusers develop cirrhosis. Alcohol liver disease is the leading cause of liver-related deaths in the United States. Women who abuse alcohol are more susceptible to alcoholic liver disease than are alcohol-abusing men and have a higher rate of mortality from alcohol-related cirrhosis.

Liver disease is related to increased levels of cytokines, the body's chemical signals that develop in response to injury, infection, or inflammation. These increases can cause injury or death to cells. Increases and/or imbalances in the production of different types of cytokines are related to all three types of liver disease: fatty liver, alcoholic hepatitis, and cirrhosis. As the name suggests, *fatty liver* involves excess deposits of fat in the liver, which often occur as a function of short-term heavy drinking. However, it rarely causes illness and is reversible if the individual stops drinking. Obesity also is a risk factor for fatty liver. *Alcoholic hepatitis* involves inflammation of the liver and death of liver cells. Symptoms include fever, jaundice, and abdominal pain. Even after withdrawing from alcohol, alcoholic hepatitis may not reverse its course and in some cases becomes worse. Alcohol cirrhosis is a progressive liver disease in which the internal structure of the liver becomes scarred and the lobules of the liver become damaged. These

morphological and functional changes can lead to liver failure and death.

Alcohol abuse and dependence also are related to disorders such as the hepatitis C virus (HCV), which also damages the liver.

### Reproduction and Fetal Alcohol Syndrome

Men who meet criteria for alcohol abuse and dependence often experience hormonal changes, such as decreased testosterone, which are associated with decreased libido, impotence, atrophy of the testes, and decreased fertility. Research with male animals has indicated that chronic exposure to alcohol results in fewer offspring, increased mortality of offspring, and lower testosterone levels in male offspring. Women's heavier drinking also has been associated with hormonal changes, although the link between alcohol use and increased levels of estrogen is still being studied. Women who meet criteria for alcohol abuse and dependence often report problems with sexual dysfunction as well as a variety of gynecologic and obstetric problems, including menstrual problems and miscarriages.

One commonly cited long-term health effect of alcohol use occurs not to the individual who consumes the alcohol, but rather to her offspring. Alcoholic women who drink excessively during pregnancy may produce offspring who exhibit a syndrome that is manifested in physical (e.g., growth deficiency, craniofacial defects) and psychological (e.g., mental retardation) deviations relative to children without alcohol exposure. Long-term follow-ups of children diagnosed with fetal alcohol syndrome (FAS) suggest that effects such as poor intellectual and academic functioning (related to their lower than normal IQ), physical problems, and maladaptive behavior continue through adolescence and young adulthood. Less dramatic fetal alcohol effects (FAEs) can sometimes occur for children of women who drink heavily during pregnancy. However, FAEs (e.g., cognitive deficits such as reduced attention and slower reaction times) are quite variable and can be subtle and difficult to diagnose. These variations in the effects of alcohol reflect variations in women's patterns of consuming alcohol (e.g., steady vs. binge drinking), the amounts they consume, and the distribution and metabolism of alcohol in their bodies, as well as the fetal developmental period during which exposure occurs. Conducting and interpreting research regarding the fetal effects of alcohol require consideration of the

contributions of factors other than the toxic effects of alcohol and its metabolites. The lives and pregnancies of heavy-drinking and alcoholic women may be affected by the women's being of lower SES, disruptive/unstable home environments, poor nutrition, the use of other drugs, prenatal infections, and a variety of other factors that contribute to the occurrence of fetal effects associated with FAS and FAE.

## ALCOHOL ABUSE AND DEPENDENCE: TREATMENT

---

Despite advances in its understanding and treatment, alcohol abuse remains a challenge for individuals and professionals, as well as an important public health problem. Treatment for alcohol abuse has a long and complex history. Over time, many models have been proposed to conceptualize and explain alcohol abuse and its problematic effects, as well as to guide the development of treatment approaches.

In the past, treatment practitioners often were trained to employ only one treatment modality based on the disease model of alcoholism, whereas presently, an eclectic approach is considered most appropriate. Furthermore, the use of single, traditional paradigms have often failed to address the complexity of the individual's motivation to change. Providing treatment appropriate to an individual's readiness to change, as well as co-occurring disorders, and designing a treatment plan that is most effective for the individual, may prove most helpful. The following list of brief descriptions of various treatment approaches is by no means exhaustive, but should give the reader an idea of what is available.

## SELF-HELP

Utilizing personal resources or seeking the help of others with similar problems, referred to as *self-help* or *mutual aid*, has become a common source of assistance for individuals with alcohol problems. Support may be found in a group format with other recovered or recovering problem drinkers, such as with Alcoholics Anonymous (AA), the earliest contemporary and most well-known self-help organization, founded in 1935 with groups throughout the world. AA and similar groups often have several things in common, such as voluntary participation, membership for anyone who wishes to stop drinking, and a variety of meeting formats, which may include speakers. Many self-help groups such as AA employ a 12-step model toward recovery, with members following the 12 steps with abstinence as the primary goal, as they receive strong support and ideas for how to cope with life's problems without alcohol. In addition, family members and friends may attend their own support groups.

AA may be differentiated from other group models by its emphasis on abstinence as the only viable goal, as well as its conceptualization of alcoholism as a disease for which individuals do not have voluntary control. In addition, AA is a spiritual fellowship where members rely on a "higher power" to help them through recovery. Examples of the 12 steps to recovery are Step 1, We admitted we were powerless over alcohol—that our lives had become unmanageable, and Step 5, Admitted to God, to ourselves and to another human being the exact nature of our wrongs.

Smart Recovery (SR), originally based on the work of Albert Ellis and "rational recovery," is another self-help program that uses professional assistance in addition to role models and fellow members who are working to change or already have changed their own drinking behavior. Unlike AA, SR emphasizes self-reliance rather than reliance on a higher power. Other key components of SR are enhancing motivation, learning to refuse to act on urges, managing life difficulties in a sensible manner without alcohol or other substances, and developing a healthy and balanced lifestyle overall. Furthermore, SR does not view addiction as a disease, but rather as a complex maladaptive behavior over which one has control and can change. To aid this change, a cognitive-behavioral (thinking/doing) strategy is used to help people learn to manage beliefs and emotions that lead to drinking.

Other self-help groups offer flexibility in goals for changing drinking behavior, supporting an individual's choice to choose abstinence or moderation. Moderation Management (MM) is an example of such a program. It employs a behavioral change model and a national support group network for people who have decided to reduce their drinking and make other positive lifestyle changes. MM empowers individuals to accept personal responsibility for choosing and maintaining their own path. The program also promotes early self-recognition of risky drinking behavior, when moderation is an achievable goal. MM provides information about alcohol, drinking guidelines and limits, drink monitoring exercises, goal setting techniques, and other self-management strategies. Members also follow a nine-step paradigm to help them achieve balance in other areas of their lives. Furthermore, harm reduction is seen as a worthwhile goal, particularly when the complete elimination of harm or risk is not a realistic option.

## PROFESSIONAL TREATMENT

### Outpatient

Although residential treatment is available, the majority of professional assistance for alcohol abuse and related problems occurs in outpatient settings, such as in clinics or medical centers.

Brief interventions entail minimal intervention by a professional, usually only a few hours, and have mostly been used with individuals who do not have more severe alcohol problems. Brief interventions often include a motivational enhancement component and personal assessment feedback about drinking patterns. The content of brief interventions varies, with many including training in coping skills, identifying cues that may lead to drinking, and refusal skills. For example, primary health care physicians may employ motivational interviewing when a patient screens positive for problematic alcohol use. Motivational interviewing is a way to help people recognize their present or potential problems and encourage them toward change when they might be ambivalent or reluctant. College campus-based programs are another example of brief interventions, where students learn skills to help them cope with peer pressure and make healthier and safer alcohol-related choices.

Behavior therapy techniques are based on the principles of classical and operant conditioning,

where drinking is defined as a learned behavior that can be modified using behavioral interventions. With operant conditioning, positive reinforcement and negative reinforcement shape the strength of associations with alcohol. Drinking may be positively reinforcing because of its euphoric effects, or it may be negatively reinforcing by reducing feelings of tension. Classical conditioning operates through the pairing of stimuli. Just as Pavlov's dogs began to salivate to only the sound of a bell after the bell sound had previously been paired with the presentation of food, heavy drinkers often have an automatic, conditioned response to alcohol cues, which enhances craving and consumption. Examples of different behavioral strategies based on operant and classical learning include cue exposure and aversion therapies. In cue exposure, based on operant conditioning, individuals are exposed to external and internal cues that often lead to drinking, such as a craving for alcohol in a particular place (e.g., a bar) or a craving in response to anxiety. With graded increases of prolonged exposure, the cue loses its potency in the extinction process and no longer compels the individual to drink. Often therapists may teach individuals how to cope with urges or cravings that are associated with cue exposure. Aversion therapies are intended to develop a classically conditioned aversive response to alcohol, and may involve sight, taste, smell, or thoughts of alcohol. The oldest of these strategies involves pairing drinking with a nausea-inducing agent, such as an emetic medication. Through classical conditioning, the individual develops nausea in response to alcohol.

Cognitive approaches to treating alcohol operate under the assumption that thought patterns contribute to increased drinking and psychological dependency on alcohol. For instance, negative mood states that cue drinking may result from misperceptions of events and negative thinking. A simple example is thinking about a difficult day; one may think, "I've had a hard day, how terrible. I owe myself a drink." Such thoughts occur automatically and often precede habitual behavior. Cognitive therapies teach individuals to identify automatic thoughts, to devise alternative constructions, and to change subsequent drinking.

Cognitive approaches also inform individuals about how their expectancies and attributions about the effects of alcohol contribute to drinking. For example, many people expect alcohol to produce pleasurable effects. This may encourage drinking and

reliance on alcohol as a "magic elixir" that transforms life's daily hassles into a "golden glow."

In cognitive-behavioral treatment, cognitive methods are combined with behaviorism. For example, with a relapse prevention approach, patients learn to anticipate and cope with situations in which there is a high risk for relapse (e.g., feeling angry). Here the patient is taught an effective coping strategy (e.g., anger management skills) as an alternative to drinking. In addition, behavioral homework assignments where an individual enters progressively more risky situations while exercising alternative coping skills assist an individual to maintain his or her treatment goals. If relapse occurs, an individual modifies his or her attributions about why the relapse occurred, focusing on the event as a "mistake" as opposed to a "loss of control."

Another avenue for treatment involves significant people in the drinker's life. Relationship therapies, such as with family members or partners, attempt to reduce drinking problems by improving the quality of relationships. Many problem drinkers experience extensive difficulties in their primary relationships. Drinking behavior is often related to such difficulties, in that individuals may drink to cope with problems, and drinking may directly contribute to such problems. A common behavioral approach in relationship therapies is to teach better communication skills and increase positive reinforcement within the relationship. Positive marital and family adjustment is associated with better treatment outcome.

Pharmacotherapies come in two forms. First, antidipsotropic medications, also known as alcohol-sensitizing or deterrent drugs, are used to deter drinking by producing an unpleasant reaction if the person ingests alcohol. One commonly used medication for this purpose is disulfiram or Antabuse. Following ingestion of alcohol, a person taking disulfiram may experience dizziness, flushing, nausea, vomiting, and other reactions. Such medications are not primary treatment by themselves, but are intended for use in multimodal programs. Second, pharmacotherapy may also involve the use of psychotropic medications to decrease cravings, treat co-occurring disorders such as depression, or lessen the severity of withdrawal. Psychotropic medications, such as Naltrexone and benzodiazepines, are also intended as adjuncts to behavioral and psychosocial therapies.

Finally, the community reinforcement approach (CRA) to treatment for alcohol problems focuses on

replacing the rewarding aspects of drinking with the rewarding aspects of sobriety. CRA is a behaviorally based, intense approach with rapid interventions affecting many areas of a person's life. For instance, a CRA program may include antidipsotropic medication, relationship counseling, vocational assistance, and social skills training. This approach also provides a method of assistance through a concerned family member or other individual when the drinker is not willing to seek treatment.

### Inpatient

Residential treatment was once considered state-of-the-art treatment and often employed before less intense forms of intervention. Now, residential treatment is considered most appropriate for individuals who have co-occurring disorders, are a risk for suicide or pose a violent risk to others, or have more serious health problems that would benefit from residential care. The standard model, often referred to as the Minnesota model, was created in a state mental hospital in the 1950s and spread first to a small not-for-profit organization called the Hazelden Foundation and then throughout the country. The key elements of this treatment method are an in-facility stay of up to 28 days; an abstinence-based, 12-step approach involving group and individual therapy; and a blending of professional and trained nonprofessional (recovering) staff. This approach is no longer widely used due to managed care, lack of insurance, and no evidence of its superiority over outpatient and alternative science-based treatments.

### Selecting a Treatment Approach

How does one choose the best treatment modality and setting? Research has been limited in addressing the question of which approach is best. Studies with sound methodology are sparse, and those with strong methodology have produced contradictory findings. One prominent, long-term study, Project MATCH (Matching Alcohol Treatments to Client Heterogeneity), compared three different treatment modalities, cognitive-behavioral therapy (CBT), motivation enhancement therapy (MET), and 12-step facilitation therapy (TSF), matched to a range of different client groups. At 2- and 3-year follow-ups, researchers found no differences among the three modalities. The only predictor was therapeutic alliance.

Therefore, if matching is not demonstrated, perhaps we need to introduce more consumer options, a menu of treatment choices. It may be best to combine different approaches based on assessment of the individual, and to employ a stepwise model, addressing motivation for change. We must recognize the usefulness of integrating different approaches and provide the individual seeking help with accurate, honest descriptions of the options available. Individuals then may choose which approach works best for them, and move on to another approach if that one does not help or fit the individual.

## ALLOSTASIS, ALLOSTATIC LOAD, AND STRESS

---

There is a need to develop a biological framework in which to conceptualize and measure the cumulative impact of social status, income, education, working and living environments, lifestyle, health-related behaviors, and stressful life experiences on physical and mental health and the progression of a number of diseases. Such a framework would aid social scientists in studying important questions, such as how socioeconomic status (SES) gets "under the skin" and affects health. This has been a major effort within the MacArthur Foundation Research Network on Socioeconomic Status and Health.

One of the main challenges has been to expand beyond the limitations and ambiguities imposed by the terms *stress* and *homeostasis*. This entry discusses the physiology of the response to stress in terms of a new formulation involving two concepts, namely,

*allostasis* and *allostatic overload*. We believe that these two terms allow for a more restricted and precise definition of *stress* that refers to an event or series of events that evoke a set of behavioral and physiological responses. These terms also clarify inherent ambiguities in the concept of homeostasis, and we also note the ways in which they replace and clarify aspects of the “general adaptation syndrome” as formulated by the late Hans Selye. A primary reason for clarifying terminology is to allow development of a more relevant set of measurements of the biological states that are related to resilience or to disease. Besides discussing the concepts and pathophysiology associated with allostatic overload, this entry also discusses the choice of biological mediators that can be measured in body fluids or by other relatively simple and noninvasive means on human subjects.

## DEFINITION OF TERMS

*Stress*—a threat, real or implied, to homeostasis. Stressors are those events and experiences that evoke behavioral and physiological response that initially protect and reduce the danger.

*Homeostasis*—stability of physiological systems that maintain life; used here to apply strictly to a limited number of systems such as pH, body temperature, glucose levels, and oxygen tension that are truly essential for life and are, therefore, maintained over a narrow range.

*Allostasis*—achieving stability through change. A process that maintains homeostasis (see above), even though the “set points” and other boundaries of control may change with environmental conditions. There are primary mediators of allostasis such as, but not confined to, hormones of the hypothalamic-pituitary-adrenal (HPA) axis, catecholamines, and pro- and anti-inflammatory cytokines.

*Allostatic state*—altered and sustained activity levels of the primary mediators (see above) that integrate energetic and associated behaviors in response to changing environments, challenges such as social interactions, weather, disease, predators, pollution, and so forth. Originally proposed for understanding physiological aspects of drug abuse, an allostatic state results in a chronic imbalance in the primary mediators reflecting excessive production of some, and inadequate production of others. Allostatic states can be sustained for limited periods if food intake and/or stored energy such as fat can fuel homeostatic

mechanisms (e.g., bears and other hibernating animals preparing for the winter).

*Allostatic load and allostatic overload*—*Allostatic load* is the cumulative result of an allostatic state (e.g., fat deposits in a bear preparing for the winter). Within limits, it is part of adaptive responses to seasonal and other demands. However, with additional unpredictable events in the environment, disease, and adverse social interactions, allostatic load can increase dramatically. When allostatic load continues for longer periods and becomes independent of the need for survival, then symptoms of *allostatic overload* appear. Abdominal obesity is an example of this condition.

## WHAT DO WE MEAN BY STRESS?

Stress is often defined as a threat, real or implied, to homeostasis, and homeostasis refers to the maintenance of a narrow range of vital physiological parameters necessary for survival. In common usage, stress usually refers to an event or succession of events that cause a response, often in the form of “distress” but also to a challenge that leads to a feeling of exhilaration, as in “good” stress. But the term *stress* is full of ambiguities. It is often used to mean the event (stressor) or, sometimes, the response (stress response). Furthermore, it is frequently used in the negative sense of “distress,” and sometimes it is used to describe a chronic state of imbalance in the response to stress. Here, *stress* will be used to refer to the *stressor*, that is, events that are threatening to an individual and that elicit physiological and behavioral responses.

The most commonly studied physiological systems that respond to stress are the HPA axis and the autonomic nervous system, particularly the sympathetic response of the adrenal medulla and sympathetic nerves. These systems do more than respond to stressors even though they are frequently identified as “stress responsive systems.” They have a housekeeping function and play an important role in the diurnal rhythm of sleep and waking activity. They are elevated by lifestyle factors such as diet, alcohol consumption, smoking, and sleep deprivation. Stressful experiences can cause sleep loss and promote drinking, smoking, and overeating, thus compounding the activation of the HPA axis and sympathetic nervous system by the stressor itself. Another type of reaction to a potentially stressful situation is enhanced anxiety, particularly

when the threat is ill-defined or imaginary and when there is no clear alternative behavioral response that would end the threat. The HPA axis and sympathetic responses act as a “funnel” and final common path through which all of these influences converge to affect an individual’s physiology.

## HOMEOSTASIS AND ALLOSTASIS

Homeostasis, in a strict sense, applies to a limited number of systems such as pH, body temperature, and oxygen tension that are truly essential for life and are, therefore, maintained within a narrow range, as a result of their critical role in survival. These systems are not activated or varied in order to help the individual adapt to its environment. Other systems that vary according to demand, such as the HPA axis and autonomic nervous system (ANS), actually help maintain those systems that are truly homeostatic. Moreover, large variations in the HPA axis and ANS do not lead directly to death as would large deviations in oxygen tension and pH.

Allostasis is a term first introduced to characterize how blood pressure and heart rate responses vary with experiences and time of day and also to describe changes in the set point of these parameters in hypertension. The change in set point was used as the primary example that distinguishes allostasis from homeostasis. Yet there is a much broader implication, namely, that allostasis is the process for actively maintaining homeostasis. Therefore, allostasis is a much better term for physiological coping mechanisms than is homeostasis, which should be reserved for the parameters that are essentially maintained for survival. Allostasis also clarifies an inherent ambiguity in the term homeostasis and distinguishes between the systems that are essential for life (homeostasis) and those that maintain these systems in balance (allostasis).

## FROM ALLOSTASIS TO ALLOSTATIC STATES, ALLOSTATIC LOAD, AND OVERLOAD

The HPA axis and sympathetic nervous system are two of the major systemic mediators of allostasis, and their secretions occur according to two major patterns: (1) in response to challenge or demand, as in stressful experiences, or (2) as part of a housekeeping function that is governed by such things as the day-night light-dark cycle. When the response pattern is either elevated or reduced in a persistent way, we call it an *allostatic state*. The overexposure or underexposure to

mediators of allostasis results in various types of cumulative change (*allostatic load*) that can lead to pathophysiology (*allostatic overload*). Four types of allostatic states are recognized.

First, chronic stress promotes allostatic load and overload (“repeated hits”). For instance, people who have had excessive stress in their lives, as measured by multiple periods of poverty-level income, show earlier aging, more depression, and an earlier decline of both physical and mental functioning. Second, most people show adaptation of physiological responses with repetition of the same type of stressor, but others do not (“lack of adaptation”); this results in an overexposure to mediators; for example, measurement of cortisol in a repeated public speaking challenge revealed individuals who did not habituate, and these individuals, who lack self-confidence and self-esteem, may well be overexposing their bodies to stress hormones under many circumstances in daily life that do not overtly disturb other individuals. Third, allostatic states also include patterns of response that are distorted, for example, impaired shut off or an elevated or a flattened diurnal rhythm of the mediator (“prolonged response” and “inadequate response”). These response profiles may be influenced by genetic factors, early developmental influences, or the effects of lifestyle and may be distorted by overuse into abnormal temporal patterns in which the body fails to efficiently manage the response to challenges or maintain a normal diurnal rhythm. As one example of a prolonged response, individuals with a genetic load, that is, two parents who are hypertensive, show prolonged elevation of blood pressure in the aftermath of a psychological stressor. Another example pertains to the diurnal rhythm, which is normally elevated in the morning and low in the evening: Reduced amounts of sleep for a number of days results in elevated cortisol levels during the evening hours. Sleep deprivation and elevated diurnal levels of cortisol are also features of major depression. In depressive illness, loss of bone mineral density has been reported that is linked to elevated diurnal glucocorticoid levels. The loss of bone minerals and muscle protein are two of the recognized consequences of chronic elevation of glucocorticoids. The elevation of cortisol in the evening also causes dysregulated glucose metabolism with evidence of a hyperglycemic state.

An example of an inadequate response occurs when the glucocorticoid response is inadequate to the needs of the individual genotype, resulting in excessive activity of other allostatic systems such as the inflammatory cytokines, which are normally

contained by elevated levels of cortisol and catecholamines. For example, Lewis rats, which have a genetic deficiency in glucocorticoid levels, are vulnerable to inflammatory and autoimmune disturbances that can be overcome by giving exogenous glucocorticoids. Comparable human disorders in which lower-than-needed cortisol may play a role include fibromyalgia and chronic fatigue syndrome.

Allostasis and allostatic load are organizing principles that apply to many biological mediators. Protection or damage are the extreme consequences of the release of mediators of allostasis, such as adrenal catecholamines and glucocorticoids, which provide some of the best examples to date of allostasis and allostatic overload. Other mediators in the blood are the adrenal androgen, dehydroepiandrosterone (DHEA), and the pro- and anti-inflammatory cytokines that are produced by immune cells and other cells and tissues throughout the body. Whereas DHEA is a functional antagonist of glucocorticoid actions, the cytokines are mediators that regulate the immune response and also play a major role as hormones involved in tissue inflammation and oxidative stress.

Although mediators in blood are the ones that are most frequently sampled in studies on human subjects, it is important to note how tissue mediators of allostasis also play an important role in allostatic load and overload. For example, the increase in levels of extracellular glutamate in the hippocampus during restraint stress is involved in remodeling of dendrites of hippocampal pyramidal neurons. This mechanism becomes less efficient as rats age. When aging rats are subjected to restraint stress and microdialysis, there is an exacerbation of both the level of extracellular glutamate and a prolongation of the response after the stress is terminated. This constitutes an example of an allostatic state in which the elevation of a mediator of allostasis fails to go back to baseline when the stressor is finished. This pattern of prolonged response can lead to allostatic load at the tissue level, since the elevated glutamate is likely to potentiate the morphological and other effects that occur through activation of NMDA and other excitatory amino acid receptors. Allostatic overload in the hippocampus involves damage and neuronal loss.

#### MEASUREMENT OF ALLOSTASIS, ALLOSTATIC STATES, AND ALLOSTATIC LOAD

How can we measure allostasis and its consequences in terms of allostatic states and allostatic

load, particularly when it comes to following the events that lead to disease over the life course in individual human subjects and groups of individuals? This is a major goal of the biologist in working with social scientists in attempting to answer questions, such as the relationship between working, living environments and socioeconomic conditions and health or disease. It is one of the main reasons that the definition of terms should be made more precise. The distinction between allostatic states and allostatic overload provides two different types of endpoints that can be measured, at least in principle. Allostatic states refer to the response profiles of the mediators themselves, whereas allostatic overload focuses on the tissues and organs that show the cumulative, pathophysiological effects of overexposure to the mediators of allostasis, either because of too much stress or because of perturbation of the housekeeping functions of these mediators. This section will briefly consider the challenges and opportunities in measuring allostatic states and allostatic load.

For determining different allostatic states in human subjects, the choice of which mediators to measure depends, in large part, on where in the body one is able to measure them as noninvasively as possible. This can be done most easily by collecting urine or saliva, but, if necessary, blood, and rarely and under special circumstances, cerebrospinal fluid can be obtained.

The choice is dictated by such factors as the size of the study, cost of the assays, and not wanting to disrupt the lives of the subjects under study more than absolutely necessary in order to ensure cooperation and minimize added stress and anxiety that can influence the secretion of the mediators being measured. This limits the choice to the circulating mediators such as glucocorticoids, DHEA, catecholamines, and certain cytokines. Salivary assays are particularly attractive, but then the question arises as to how to sample over time to get an adequate representation of a dynamic system, since the levels of the mediators may fluctuate during the day and night. This is a topic unto itself and has been the subject of a number of methodological studies (see Web site for MacArthur SES and Health Research Network: [www.macses.ucsf.edu/](http://www.macses.ucsf.edu/)). Portable monitoring of blood pressure and heart rate provide complementary information to the measurement of mediators in body fluids. The ease of such measurements also explains why the study of cardiovascular function as an endpoint of disease has

progressed so far relative to other systems of the body that are sensitive to stress and show allostatic load.

As far as assessing allostatic overload, the fundamental issue is determining which parameters best assess cumulative pathophysiological changes in key systems, such as the heart and brain. Endpoints, besides the mediators discussed above, that have been used for cumulative assessment of allostatic overload in different systems of the body, include waist-hip ratio, glycosylated hemoglobin and cholesterol and HDL. Other cumulative measures include measurements of shrinkage of key brain structures like the hippocampus and assessments of bone mineral density and skeletal muscle mass.

In previous research, Seeman and colleagues have demonstrated that an initial operationalization of allostatic load, based on information reflecting functioning of the hypothalamic-pituitary-adrenal axis, sympathetic nervous system, cardiovascular system, and metabolic processes, is related to risks for a range of different pathology, including risks for incident cardiovascular disease, declines in cognitive and physical functioning, and mortality. The initial index of allostatic overload (AL) was designed to summarize levels of physiological activity across multiple regulatory systems pertinent to disease risks and was based on an algorithm whereby, for each of 10 biological parameters, subjects were classified into quartiles based on the distribution of scores in the cohort. AL was measured by summing the number of parameters for which the subject fell into the “highest” risk quartile (i.e., top quartile for all parameters except HDL cholesterol and DHEA-S for which membership in the lowest quartile corresponds to highest risk) so that the range of possible scores was 0 to 10. More recently, Seeman and colleagues have explored alternative approaches to summarizing information across these multiple biological parameters, including canonical correlation analyses, which incorporated the full range of biological values for each parameter and allowed for unequal weighting of the various parameters. Results of these latter analyses demonstrated even stronger associations between the summary measure of allostatic load and prediction of subsequent risks for decline in cognitive and physical functioning.

In addition to such evidence, linking various indices of allostatic overload to subsequent health risks, research has also demonstrated that differences in AL among middle-aged and older adults are related in expected ways to both SES, as well as differences

in social conditions (e.g., levels of social integration and social support)—higher SES and better social conditions being associated with lower allostatic load. These findings have also been replicated in a younger cohort (ages 18-32) where parental SES (measured in terms of educational attainment) has been found to be negatively associated with a summary index of cardiovascular risk in Caucasians.

Clearly, the measures of AL outlined above represent only an initial, and only partial, assessment of the concept. Further evaluation of the concept of allostatic overload will require attention to a number of issues related to measurement. First, what would be the a priori set of component measures needed to comprehensively assess AL (i.e., which regulatory systems and which parameters of those regulatory systems, including both system dynamics and system “state/level” assessments)? Measurements of AL based on work by Seeman and colleagues have, to date, not included assessments of hemostatic or inflammatory parameters, or assessment of parasympathetic activity; nor do they encompass assessments of system dynamics.

A second issue for future research concerns the procedures for developing optimal operational measures of AL from these component measures. Previous research has relied largely on linear analysis techniques. Future research is likely to gain from exploration of the potential value of more nonlinear techniques such as recursive partitioning that permit identification of nonlinear patterns of association between the various components of AL and greater versus lesser health risk.

## ALZHEIMER'S DISEASE: PSYCHOSOCIAL ASPECTS FOR CAREGIVERS

---

Alzheimer's disease (AD) is one of the most significant health issues in late life, affecting the health and well-being of both individuals and their families. Currently, the estimates of prevalence of AD in the United States range from 2.7% to 11.2% for people 65 years of age or older, or approximately 1.5 to 6.1 million individuals. Importantly, 75% of all dementia victims who are 65 years of age or older have AD. Estimates of the direct costs of AD, including nursing

homes, long-term mental hospitals, paid home care, physician care, acute hospital care, and caregiver medical care, exceed \$60 billion per year in the United States. Yet the costs of AD extend beyond the financial toll.

## ALZHEIMER'S DISEASE DIAGNOSIS

AD is an age-related disease that involves the gradual onset of progressive global intellectual and functional deterioration. It is diagnosed primarily using the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* criteria. Persons with AD have impaired short-term memory, attention span, and cognition, especially abstraction, calculation, judgment, and spatial relations. They also can exhibit affective problems, such as depression, and anger, as well as behavioral problems, such as agitation, paranoia, wandering, and aggression. During differential diagnosis, AD is distinguished from short-term loss of intellectual function, delirium, vascular disease, focal neurological signs, myocardial infarction, alcoholism, major psychiatric illness, degenerative neurological diseases, chronic renal, hepatic, pulmonary, or endocrine disease, and central nervous system disorders.

The course of AD, ranging from 4 to 15 years, is characterized by a progressive decline in cognition, affecting multiple functional domains—ability to manage activities of daily living (ADLs), social and emotional competence, judgment and decision making, way-finding, memory, language, and ultimately, control of physical functions (e.g., walking, continence). Because AD affects all aspects of functioning, this disease has significant implications for families, who provide the vast majority of care.

## PSYCHOSOCIAL IMPLICATIONS OF ALZHEIMER'S DISEASE

During the early phases of AD, the individual is aware of changes in cognition, and commonly experiences emotional responses of denial, anger, fear, anxiety, and sadness. With progression, other psychosocial symptoms can emerge, including comorbid depression and anxiety, agitation, lowered stress threshold, and social withdrawal.

Most family caregivers of persons with AD face years of continuous exposure to physical and psychosocial demands. Caregiving represents not only

the donation of time and energy but also potential loss of income and/or accrued benefits when caregivers make work adjustments to accommodate their role. Many working caregivers change work schedules, while a small percentage take a leave of absence, seek a less demanding job/fewer hours, or give up work. Almost half of all caregivers are adult children, the "sandwich generation," who are providing support to both younger and older family members, while at the same time dealing with competing demands of employment and other activities.

By providing over 80% of all long-term care, family caregivers make a substantial contribution, offsetting the potential expenditures should older adults require formal services instead. The market value of this care by unpaid family members and friends was estimated to be approximately \$196 billion in 1997, dwarfing concurrent national spending on formal home health care (\$32 billion) and nursing home care (\$83 billion).

Caregiving also poses physical, psychological, emotional, social, and financial burdens. The diagnosis of AD is an acute stressor that yields short-term psychological distress; however, the diagnosis is revisited and its effects are chronic as the AD unfolds and the caregiver experiences ongoing reactions. Depression is a fairly common outcome of caregiving, occurring at rates higher than the general population, with estimates ranging from 7% to 36% of caregivers. Responses to the caregiving situation vary considerably, depending on caregiver vulnerability and strengths, the demands of the care situation, social support, characteristics of the care recipient, the type and quality of the dyad's relationship, and health.

## PHYSICAL HEALTH IMPLICATIONS OF ALZHEIMER'S DISEASE

One would expect a number of caregivers to be at elevated risk for health problems because chronic stressors are associated both with illnesses and with disease progression in persons who are already ill. In fact, caregivers may experience prolonged anticipatory bereavement over lost aspects of their relationships with their care recipients, and bereavement is positively associated with physical illnesses, health care utilization, and mortality. Unfortunately, for many years, caregiver research focused more on psychological rather than on physical health problems, and with the advent of research on physical health, the

primary emphasis was on self-reported health. This included global health, and reports of medication use, symptoms, utilization of health care, and illnesses. Relationships between caregiving and reported health were expected because strong positive relationships exist between caregiving and psychological distress and between distress and reported health problems.

Other pathways may, however, also predict relationships of caregiving with illness. For example, it is well known that chronic stress and bereavement are associated with elevated physiological risks and that such risks may arise in several ways. In one pathway, distress triggers risky behaviors, such as poor diet, sedentary behavior, and substance abuse, which elevate physiological risk. In another pathway, chronic stress leads to psychosocial distress and then to elevated stress hormones. This occurs via the hypothalamic-pituitary-adrenal axis, from which CRH-ACTH-cortisol are secreted, and the sympathetic adrenomedullary axis, from which norepinephrine and epinephrine are secreted. These hormones stimulate peripheral activity, which can lead to *allostatic load* or wear-and-tear from repeated arousal and inefficient control of physiological responses. Such compensation may lead to pathophysiology. These pathways contribute to illness by increasing cardiovascular, metabolic, or immunologic dysregulation, and they help to explain why depression, sleep problems, and risky behaviors increase a caregiver's risk for illnesses. Indeed, caregivers report more sleep problems, poorer diets, and sedentary behaviors than do noncaregivers.

In terms of physiological functioning, research on caregivers began only 15 years ago. Since then, studies have assessed stress hormones and neurotransmitters, immunologic, cardiovascular, and metabolic functioning. A recent quantitative review examined 23 independent studies from around the world that compared physical health indicators in 1,594 family caregivers of persons with dementia to health indicators in 1,478 age- and gender-matched noncaregivers. Overall, caregivers showed poorer self-reported health. Furthermore, across several studies, caregivers had a 23% higher level of stress hormones (e.g., cortisol) and a 15% lower level of antibody responses than did noncaregivers. Physiological reactions to elevated stress hormones, such as elevated blood pressure and glucose, may increase a caregiver's risk for hypertension and diabetes. Moreover, suppressed antibody production may be serious because the mean age

of caregivers and noncaregivers in this review was 65.1 years. Older adults are at higher risk for influenza, and their responses to vaccination are lower than in younger adults. The results of this review may partially explain why one study showed that over an average of 4.0 years, spouse caregivers were, in fact, more likely to die than spouse noncaregivers.

## IN SEARCH OF THEORETICAL MODELS

Although research on caregiver health has steadily increased in the past decade, few attempts have been made to use a theoretical model to unify this work. Such models may help researchers and policymakers to focus on those caregivers at greatest risk for health problems, that is, those caregivers who contributed most to the differential percentages cited above. The fact is, the majority of caregivers may not find caregiving highly distressing, but ongoing demands and exhaustion, particularly for frail caregivers, can result in deleterious health outcomes for those who are vulnerable.

One explanatory model attempts to focus on these caregivers. It considers pathways that interrelate caregiver stressors, psychosocial distress, risky health habits, physiological mediators, and subsequent health problems. Importantly, it includes individual differences, such as vulnerabilities and resources, which moderate relationships of stressors with distress. Here, vulnerabilities are enduring hard-wired influences such as personality, gender, ethnicity, family history, trait anger, and comorbidities. In contrast, resources are more mutable and affected by the person and the environment. These include social supports and coping. Interactions of vulnerabilities and resources with exposure to stressors (caregiving) are expected to influence illness over and above the direct effects of any one of the variables. Indeed, in one study caregivers with high vulnerability and low resources had greater burden 15-18 months later than did those with either low vulnerability or high vulnerability and high resources, even after controlling baseline burden. One would expect such distress to result in greater illness risks for these caregivers.

## CAREGIVER VULNERABILITIES AND RESOURCES

Demographic variables, such as a caregiver's age, relationship to the care recipient, and gender, may be particularly relevant to his or her risk of illness.

Interestingly, the direction of moderation is not obvious for age and one's relationship to the care recipient. Although older persons have less resistance to illness, caregiving may be more developmentally on time for older than for younger caregivers. Also, partners may be frailer, more isolated, and more distressed than other caregivers, but caring for a partner might be viewed as a marital commitment. In contrast, caring for a parent might pose conflicts of equity when one must choose between parents and partners/children.

Relationships of caregiving with self-reported health are greater for older participants, perhaps because of the increase with age of physical illnesses and disabilities, which might be exacerbated by psychosocial distress, a strong correlate of self-reported health. One might expect gender to be a moderator of caregiver health because women report more distress and health problems, and they utilize more health care than do men. Alternatively, men exposed to laboratory stressors show larger and more consistent increases in stress hormones, neurotransmitter metabolites, and blood pressure than do women. This may be further exacerbated when faced with a stressor, such as caregiving, which is "gender-inconsistent" with traditional men's roles. Finally, widowers appear to have more illnesses in response to the loss of a spouse than do widows. It has been argued that women's biopsychosocial adaptation to stress, in contrast to that of men, is to seek out relaxation and affiliation. Women's stress reactions include nurturance to protect the self and offspring and reduce distress, and the creation of social networks that facilitate nurturance. These reactions might reduce vulnerability to stress-related illnesses.

Ethnicity may be relevant to caregiver health because it is related to health disparities and ethnic groups respond differently to caregiving. Also, African American caregivers may have fewer economic resources than Caucasian caregivers, but they may have more spiritual resources. Caregiving occurs in the context of cultural meaning, and might be perceived as having different rewards or challenges by member of different ethnic groups.

A history of depression constitutes a further vulnerability, in that 73% of caregivers with such a history had a recurrence of depression while they were caregivers, but only 30% of noncaregivers had a recurrence during a similar time frame. This is important because depression is positively related to health problems in caregivers and in the general population. Anger and

hostility are also relevant to caregiver health because anger is a risk factor for elevated blood pressure and greater body mass index, fat and caloric intake, and glucose and insulin levels. Indeed, caregivers have elevated levels of anger, and caregivers who are critical of their spouses report more trait anger than those who are not critical of their spouses. Moreover, caregivers high in anger have higher levels of fasting glucose than do controls high in anger, but no differences exist in caregivers and controls that are low in anger. Finally, comorbidities such as a history of cancer, hypertension, and coronary disease may moderate relationships between caregiving and physiological measures that are associated with these diseases.

In one analysis, caregivers with cancer histories had lower natural killer cell activity than did noncaregivers with cancer histories, but no differences existed in caregivers and noncaregivers without cancer histories. In another analysis, no effect was observed on systolic blood pressure reactivity for caregivers and noncaregivers with normal blood pressure, but hypertensive caregivers showed greater reactivity than did hypertensive noncaregivers. Also, caregivers with coronary disease had higher levels on the metabolic syndrome, a linear combination of fasting glucose, insulin, lipids, mean arterial pressure, and obesity, than did noncaregivers with coronary disease; however, no difference occurred for caregivers and noncaregivers free of such disease.

In contrast to vulnerabilities, resources such as emotional and instrumental supports are related to better health habits, less distress, and lower prevalence of coronary heart disease (CHD). High levels of perceived support also predict better-reported health in caregivers. High socioeconomic status (SES) is associated with better physical health and lower CHD prevalence, and low SES is related to poorer health in caregivers. Active coping, such as problem solving, is inversely associated with elevated distress, poor health habits, and physiological risk. Other positive factors, which involve the rewards of caregiving, have also been documented. These include a sense of meaning, meeting interpersonal obligations, pleasure in providing care to a loved one, and satisfaction. Unfortunately, the positive aspects of caregiving have not received enough attention.

## CONCLUSIONS

Family caregivers are critical to the health and support of persons with AD. It is, therefore, important that

we understand, and potentially modify, relationships between their exposure to the chronic stress of caregiving and the subsequent development of psychological or physical health problems. Caregivers with preexisting comorbidities may be at particular risk. General research on stress and illness suggests that persons with comorbidities may be at higher risk for health problems in response to stress than persons free of such morbidities. Importantly, the population of older caregivers with comorbidities is large, yet they have been largely ignored in this literature as have other subgroups defined by individual difference variables. Research incorporating assessments of individual differences and other health indicators will facilitate targeting high-risk caregivers and could be used to develop cost-effective treatments for those who can profit most from interventions. By helping caregivers to maintain their health, such interventions should also help care recipients and society.

## ANGER AND HEART DISEASE

The concept of anger as a risk factor for cardiovascular disease originated from the idea that certain behavior patterns were found more commonly among cardiac patients. At the end of the 19th century, Sir William Osler (1892), considered the father of modern medicine, noticed certain characteristics of patients with heart disease:

In the worry and strain of modern life, arterial degeneration is not only very common but develops at a relatively early age. For this, I believe that the high pressure at which men live, and the habit of working the machine to its maximum capacity are responsible [for coronary disease].

In the mid-20th century, the Type A "coronary-prone behavior" was defined by Friedman and Rosenman (1959/1974). Typical characteristics of the Type A behavior included competitiveness, excessive drive or achievement-striving, enhanced sense of time urgency, enhanced aggressiveness, ambitiousness, intense concentration and alertness, and high levels of "free-floating hostility." In 1978, this stereotype later became known as the Framingham Type A behavior. Additional descriptors for this type included pressed for time, preoccupied with work, stretched by work, uncertain/dissatisfied about your performance, eating too quickly, strong need to excel, upset when waiting, hard-driving and competitive, bossy or dominating.

However, there were conflicting studies for and against the "Type A hypothesis" as a true risk factor for heart disease. With further investigation, the

anger-hostility complex was identified as the "toxic element." According to the Structured Interview personality test, people with this complex had the potential for hostility, anger directed outward, competitiveness, anger experience, vigorous answers, irritation at waiting in lines, and explosive voice modulations. A special hostility scale was developed by Cook and Medley in 1954 as part of the Minnesota Multiphasic Personality Inventory, and included traits such as cynicism, angry feelings, and aggressive responding to provocation. Investigations over the past couple decades have focused on anger-hostility as the potentially important risk factor for heart disease.

## EPIDEMIOLOGICAL EVIDENCE

Commonly recognized components of anger include anger-out (expression, nonneurotic hostility), anger-in (suppression, neurotic hostility), and anger experience. Although studies have shown mixed results, anger-in, or the suppression of anger, competes with anger-out, or the full-blown expression of anger, as the main predictor for coronary artery disease risk. The Cook-Medley Hostility (Ho) Scale has been the most frequently used quantitative measure for anger and hostility, and high Ho scores have been related to cardiovascular disease in many studies. Other frequently used measurement tools for anger and hostility include the Spielberger Multidimensional Anger Inventory, the Framingham Anger Scale, Hostility scales of the Buss-Durkee Inventory, and subscales of various other personality tests.

Cross-sectional studies have shown that episodes of anger may "trigger" heart attacks. In the ONSET study, the risk of myocardial infarction was found to be elevated only during the first 2 hours after an outburst of anger. Several studies have demonstrated an ill effect of mental stress or anger on cardiovascular physiologic responses, such as increased blood pressure and heart rates, lower heart function, and coronary vasoconstriction.

Many prospective cohort studies have shown that anger or hostility leads to an increased risk of developing subsequent cardiovascular disease, particularly coronary heart disease, hypertension, and stroke. This relationship has been seen in the Framingham Heart Study, the Western Collaborative Group Study, Normative Aging Study, Finnish men, Danish men and women, the Caerphilly Study, the Atherosclerosis Risk in Communities (ARIC) Study, the Johns

Hopkins Precursors Study, and various student populations. This risk may be conferred in a dose-response manner. A recent report suggested that anger experienced in younger populations may increase risk for premature heart disease.

Studies to date assume that anger is a trait that remains constant over time and affects heart disease incidence uniformly throughout follow-up. However, human behavior can change over time, and so may a person's experience or expression of anger. Most studies have only been able to assess anger at limited time points, and more investigation is warranted to evaluate the more chronic effect of this potentially manageable emotion.

### POSSIBLE BIOLOGICAL MECHANISMS

Although the exact mechanism by which anger may cause cardiovascular disease remains unclear, anger may have a role in underlying atherogenesis as well as triggering clinical events. Anger increases cardiovascular reactivity as manifested by increased catecholamine levels, heart rates, and blood pressure. In recent studies, high levels of anger during anger recall have produced vasoconstriction of narrowed coronary arteries, but not of nonnarrowed arteries, suggesting that patients with preexisting disease may have blood vessels that are more reactive to anger. In patients with stable coronary artery disease, anger recall has reduced heart function (left ventricular ejection fraction and cardiac output) and increased various pressures (diastolic blood pressure and peripheral vascular resistance), more than exercise or other psychological stressors. Furthermore, anger may increase vulnerability to ventricular arrhythmias, which can lead to sudden death. Angry people have also shown increased platelet reactivity and hyperaggregability, and platelets are the blood cells typically implicated in causing heart attacks. Chronically, anger may influence risk through established cardiac risk factors, such as hypertension or depression.

### IMPLICATIONS FOR ANGER MANAGEMENT

Since the mid-1970s, various stress management techniques have been used as part of therapeutic behavioral programs to treat anger and hostility, and, in the earlier years, the Type A behavior pattern. In current practice, formal cardiac rehabilitation and exercise training programs have been shown to improve exercise capacity, plasma cholesterol levels, obesity, major morbidity, and mortality, and can reduce hostility or

angry behavior. Community studies in older populations have observed that secondary prevention efforts to reduce stress and anger have led to decreased incidence of recurrent ischemic events. Whether knowledge about anger can be translated into effective primary prevention strategies needs to be determined.

## ANGER AND HYPERTENSION

---

The causes of chronically elevated blood pressure, formally known as hypertension (HT), are not well

understood by medical scientists and practitioners although there has been a long-standing belief that mental or emotional factors may be involved. During the 1930s-1950s, psychoanalytically oriented practitioners and researchers, representing the psychosomatic movement, emphasized that mental and emotional distress can contribute to the development of physical disorders. Two leaders of the psychosomatic movement, Flanders Dunbar and Franz Alexander, proposed that inhibition of angry feelings contributes to the development of HT. They reasoned that hostile provocation typically is associated with increases in blood pressure (BP), but after the anger is expressed, BP typically decreases. However, according to the anger-suppression hypothesis, some persons are personally predisposed to suppress their rage. This leads to recurrent autonomic arousal, which eventually leads to chronically elevated BP. According to this idea, the habitual tendency to suppress angry feelings was conceptualized as a personality trait that represented a fear or anxiety about expressing anger to others. Alexander also thought that some constitutional physical predisposition and a stressful, precipitating condition, such as a serious interpersonal conflict or death of a close relative, were also necessary conditions for the development of HT, but these qualifiers have not tended to receive attention from subsequent researchers.

From its inception, the idea of a “hypertensive personality” was controversial among physicians who were skeptical about a role for emotional and mental factors in the development of HT. Although the psychoanalytic approach waned in influence, interest in this topic reemerged with the rise of behavioral medicine and health psychology. In the past three decades, nearly 50 studies testing the anger expression hypothesis have been published.

### CROSS-SECTIONAL EVIDENCE

Most studies testing this idea have been cross-sectional in design. In such studies, HTs were identified at medical clinics as a result of self-referral and constituted the “cases” whose responses on the anger scales are compared with responses of nonpatients unconnected to the medical clinic. Other studies also have been cross-sectional but sampled from larger populations and identified HTs through community screening.

Studies have used a variety of self-report measures to assess the individual’s habitual tendency to express

anger, but only a few scales have adequate validation. Charles Spielberger and Ernest Harburg developed the most popular instruments to measure personal tendencies to express (*anger-out*) and suppress (*anger-in*) anger. A general problem in this literature, however, is that there is little consensus about the best way to measure anger expression because anger is a multidimensional and thus potentially ambiguous construct. In addition, although these scales purport to assess personal reluctance to express annoyance and irritation, they also are strongly saturated with more general negative feelings. Consequently, it may not be anger-in per se that is responsible when positive results are obtained.

Narrative and quantitative reviews of the empirical literature indicate that several studies report positive associations, typically of modest to moderate strength, between anger suppression and BP, consistent with the psychosomatic hypothesis. However, the results across studies are highly variable. One recent study employing an extensive series of psychological measures, including anger expression, and assessing BP in the clinic and using an ambulatory BP monitor for 24 hours during a normal workday failed to find any significant associations between personality and BP.

### ALTERNATIVE EXPLANATIONS

Some of the positive findings have been criticized on the basis of possible participant selection bias. The reasoning is that hypertensive persons may only appear to be higher in anger-in. Psychological inventories measuring anger also tend to load heavily on neuroticism. Neurotic individuals are known to be somatically concerned, worry about their health, and are more likely to refer themselves for medical attention. Such frequent medical consultation increases the chances of detecting HT, a relatively common physical disorder. The sampling bias explanation implies that an association between anger and HT should not appear in randomly selected samples where angry-neurotic individuals should not be overrepresented. A meta-analysis assessed this possibility, but still found positive associations between anger and HT in population samples, hence reducing the likelihood of subject selection as an alternative explanation for positive results linking anger-in and BP.

It also has been speculated that the positive results may represent a “white coat effect” (i.e., when some persons show elevated BP in the clinic but normal pressures during everyday life—presumably because

they become anxious during medical examinations). Because angry persons might be prone to show greater BP responses to clinic assessment, their pressures may erroneously be interpreted as an indication of chronically elevated BP. However, a review of the results for white coaters versus non-white coaters actually showed that persons with higher pressures in the clinic but lower pressures during daily life had lower anger scores. An alternative explanation that has not been ruled out by cross-sectional studies is that being diagnosed and labeled a hypertensive person might affect personality.

### PROSPECTIVE EVIDENCE

Prospective studies that adjust for baseline BP and traditional HT risk factors should provide more rigorous scientific tests of the anger suppression hypothesis although only a small number of such studies currently are available. Most of the available studies report mixed support, at best, for the anger expression hypothesis. Moreover, some of the studies reporting supportive evidence suffer from the failure to use standardized measures of anger or to control for baseline BP, potentially serious limitations. One of the best studies found that the tendency to express anger in either direction (anger-in and anger-out) was related to subsequent HT. In the context of these disparate results for anger expression, it is interesting that five prospective studies show consistent evidence of an association between symptoms of anxiety and depression and subsequent HT. Because several anger expression measures overlap with anxious and depressed feelings, it remains a possibility that this overlap is responsible for the positive findings that have been interpreted as support for the anger expression hypothesis.

In summary, evidence for the anger suppression-HT hypothesis is inconsistent and subject to alternative interpretations. A definitive answer is unlikely to be available until several more prospective studies are available that employ standardized measures of anger expression and adjust for other negative emotions.

## ANGER: MEASUREMENT

---

A linkage of emotional factors to psychological and physical health was posited in the pre-Cartesian writings of philosophers and physicians. With theoretical and methodological advances in physiology, psychology, medicine, and sociology, prescientific speculations evolved to a rigorous examination of the scientific basis of the role of the experience, management, and expression of emotion in the etiology and pathophysiology of disease. Although inconsistent findings are reported, a body of evidence is consistent with the notion that the connection between stressors and disease can be mediated by such psychosocial factors as hostility, and the experience and expression of anger.

Because of the major impact of cardiovascular disorders on morbidity and mortality and the fact that traditional risk factors (e.g., cholesterol, smoking, obesity) cannot account for all incidences of these diseases, a large body of empirical evidence has accumulated across decades attempting to link anger and hostility to the development of heart disease and high blood pressure. Moreover, empirical analyses (viz., meta-analyses) of this literature have shed light on issues pertaining to the study of anger, hostility, and health status. Thus, as a means of elucidating measurement and conceptual issues related to investigating linkages of health status with anger and hostility, this entry focuses on an examination of the empirical literature correlating diseases of the cardiovascular system with hostility and anger experience and expression.

## DIMENSIONS OF ANGER AND HOSTILITY

Typically, hostility is defined as a cognitive set characterized by a cynical mistrust and suspiciousness of others. Within the interpersonal context, this cognitive set is thought to increase the likelihood of the experience of angry affect, including resentment, disgust, irritability, and contempt, and the subsequent behavioral expression of aggression (e.g., verbal attack, physical assault, and indirect actions such as gossip and character assassination). Anger expression has been further divided into (a) anger-out (use of overt behavior that can be viewed by others), (b) anger-in (the suppression of the overt expression of anger), and (c) constructive anger expression (an assertive and mature discussion of the interpersonal triggers of the anger). Jorgensen and colleagues created another set of distinctions; namely, anger assessments were divided into (a) interpersonal analogue assessment for measures associated with an interpersonal context (e.g., role-playing, projective tests administered by another person, use of interpersonal vignettes, and interviews), (b) reported overt reactions (e.g., self-report of anger-out, assertion, or dominance strivings), (c) covert anger reactions (e.g., anger-in and trait anger), and (d) ambiguous (a combination of reported overt reactions and covert reactions). These distinctions have proven useful in understanding the nature of anger/hostility measurement in the study of disease outcomes.

### Nature of the Association

Meta-analytic work on research correlating anger and hostility measures with heart disease outcomes shows, in general, weak associations and substantial variation between studies. Moreover, associations have been shown to vary as a function of demographics (e.g., ethnicity, age, socioeconomic status [SES]), health status (e.g., awareness vs. unawareness of high blood pressure or studying individuals with coronary heart disease [CHD] or at high risk for CHD), and type of assessment procedure.

### Categories of Covert Anger Reactions and Ambiguous

Measures of covert anger and hostility and the ambiguous category show very weak, positive associations with CHD and high blood pressure (a risk factor for CHD). A number of reasons may contribute

to these results. First, these measures (e.g., the Cook-Medley Hostility Scale [Ho]; Anger-In and Trait Anger Scales of Spielberger and colleagues) do not provide a unitary, summed score centering on a specific context. Given the importance of the interpersonal context in hostility and anger, it is possible that overall scores for covert anger and hostility do not adequately tap salient interpersonal dimensions when items basically capture a generalized affective experience. Second, respondents are asked to report on socially undesirable attributes. Thus, people may either knowingly (impression management) or unknowingly (defensive, self-deception) underreport the experience of covert anger and hostile cognition. These measures typically correlate positively with measures of social defensiveness (e.g., Marlowe-Crowne Social Desirability Scale).

Measures of covert anger also have been shown to correlate with measures of neuroticism/negative affectivity, which have been reported to (a) not correlate with heart disease, (b) be inversely related to blood pressure (BP) elevations for persons unaware of their BP status but directly related in persons aware of their BP status, and (c) correlate with angina symptoms in persons without CHD. Depending on sample composition (e.g., inadvertent selection of a high proportion of persons with high neuroticism score) scores of experiential, covert anger may be elevated due to the neuroticism factor, which may obscure associations by itself or in combination with other dimensions (e.g., BP status awareness or persons with symptoms of angina without underlying disease). Likewise, assuming that equal scores derived from summing across items represent persons of equivalent dispositional covert anger may not be tenable. For example, two people may show the same score on the Ho, but one person's score may be largely due to attributing hostile intentions to the behavior of others, whereas the other's score may be largely due to a self-description related to the affective and behavioral manifestations of hostility. Finally, these self-report measures may not provide response options germane to many respondents; that is, items may not be relevant to a respondent's way of construing her or his covert anger, which is likely to be influenced by such factors as SES, ethnicity, family background, and age.

### Overt Reactions

Although sharing the above problems with covert anger, evidence exists suggesting that reported overt

reactions also show weak associations with CHD and elevated BP. For example, it has been reported that a neurotic hostility factor (such covert reactions as irritability, resentment, mistrust, and suspicion) was unrelated to angiographically determined coronary artery disease (CAD), whereas the expression of anger/hostility (e.g., verbal or physical attacks) was correlated positively with CAD; these two dimensions were factor analytically derived from the Buss-Durkee Hostility Inventory. Regarding high BP, reported overt reactions have been shown to correlate negatively with BP levels, an association that appears augmented by age (tends to be stronger for older participants) and ethnicity (tends to be stronger for Black people relative to White people).

### Interpersonal Analogue Assessment

For both CHD and high BP, interpersonal analogue assessments show the strongest effect sizes. Interview (e.g., the Structured Interview for coronary-prone behavior) and role-playing (e.g., acting out a scenario requiring assertion of personal rights with another person) methods present potential advantages over self-report measures. First, respondents are less constrained in the range and richness of their responses to open-ended questions. Second, there can be a minimization of response error related to such factors as faulty recall, misunderstanding of items due to educational or cultural factors, or difficulty with conceptualizing the occurrence and/or intensity of ambiguous internal affective or mental states. Third, response bias related to impression management and self-deception may be decreased due to a focus on trained judges scoring behavior unbeknownst to the respondent.

All of these potential advantages require (a) highly trained and skilled interviewers or actors capable of rapport building and adjusting to the fluidity of the interpersonal transaction, and (b) highly skilled judges trained in a reliable and valid coding system. Both judges and interviewers must have a keen awareness of how demographics of the sample influence construal of and responses to interpersonal contexts.

Disadvantages relate to the labor-intensive work of finding and training conscientious and perspicacious personnel, the consistent execution of the interpersonal transaction, and potential problems with the drift of reliability across the course of the investigation. Although the focus is on coding behaviors unbeknownst to the respondent, interviews and role-playing may still be vulnerable to factors of impression

management and self-deception since social norms impose prohibitions against the improper and excessive expression of anger and hostility in most social settings, including the research context. Again, raters of the behavior must have a keen eye for the subtleties and nuances of how hostility and anger are expressed.

Use of interpersonal vignettes (e.g., those created by Harburg and colleagues) to prime responding may aid self-description of angry reactions due to the use of specific interpersonal contexts that can be conceptualized and reacted to with minimal contextual ambiguity. Like self-report measures, vignettes are convenient. However, like self-report measures, the vignette approach may be more vulnerable to social defensiveness skewing responses in a socially desirable direction.

### SUMMARY AND ALTERNATIVE CONCEPTUAL FRAMEWORK

By using cardiovascular disorders as exemplars, this entry has shown that any attempt at linking traits of hostility and anger will confront a number of challenges. These include issues related to psychometrics (e.g., a single summary score may reflect more than one dimension, despite adequate markers of reliability and validity), severity and knowledge of disease, demographics, whether respondents can understand and accurately respond to item content, type of measurement procedure, and the degree to which the measurement procedure embodies the anger-inducing context, which is interpersonal in many cases. Even though interpersonal analogue assessments hold promise of reducing a number of measurement challenges, queries and scenarios must be finely crafted to the anger-inducing context. For example, if the conceptual question relates to angry protests following diagnosis of a fatal disease, it may make little sense to query about irritation induced by a driver slowing down traffic; rather, questions concerning potential resentment over abandonment by God, friends, and family may be more on the mark.

To date, a trait emphasis has been deployed in researching relations between health and agonistic reactions. This emphasis assumes consistency of cognition, behavior, and affect across time and situations, and stresses increasing reliability by averaging or summing (i.e., aggregation) across occasions of measurement. Aggregation, in essence, considers variation across occasions as error rather than a source of information on personality.

An alternative perspective is to consider variation across situations as a coherent marker of personality functioning. In other words, by studying person and environmental factors associated with the variability of state anger occasions, a more comprehensive picture of anger expression, anger experience, and hostile attitudes in relation to interpersonal conflict may emerge and, thereby, increase the precision of predicting disease outcomes. Recall that in the prediction of cardiovascular disorders, effect sizes were best for assessment procedures grounded in an interpersonal context; nevertheless, the effects were of a modest magnitude. With current technologies, hand-held computers can be used to assess occurrence and intensity of angry reactions as BP and heart rate (HR) are measured, for example, across a workday. Variation in outcomes involving both ecological and lab assessments are likely to occur. For example, an initially healthy person who eventually develops CHD may manifest high hostility during a structured interview in the lab (SI) and then, across the workday, show a pattern of high levels of BP and HR with coextensive frequent and intense bouts of anger and anger expression, particularly in the interpersonal context. Conversely, an initially healthy person, who displays elevated ambulatory BP at work and eventually develops high BP, may show low SI hostility and then display frequent and intense bouts of anger without anger expression while at work. By reporting high levels of SI-induced anger, the former individual shows more consistency with the ecological anger reports, whereas the latter person, due to social acceptance strivings triggered within the lab context, reports low levels of state anger that are inconsistent with anger experienced at work. As suggested in this brief example, patterns of both consistency and variation hold the promise of shedding light on the complex challenge of linking anger and hostility measurement with health status.

## ANXIETY, HEART DISEASE, AND MORTALITY

---

Although many experts consider anxiety to be a universal feature of human existence, when it is chronic and persistent it may have significant consequences for both psychological and physical health. A relationship between anxiety and heart disease has been long noted by physicians. Coronary heart disease (CHD) accounts for approximately 2.2 million hospitalizations annually in the United States. The traditional risk factors (e.g., smoking, hypertension) explain only about 40% of the occurrence of CHD. There is converging evidence that chronic anxiety, in addition to causing emotional distress, strongly affects heart health. In fact, some scientists have suggested that anxiety may even influence longevity, whereby more anxious people die sooner. If anxiety indeed puts people at greater risk for heart disease or premature mortality, it is critically important that society invests in the identification and treatment of individuals affected with anxiety. This could not only ease a great deal of distress but also represent a potentially important route to disease prevention.

### THE NATURE OF ANXIETY

Anxiety is a strong negative emotion, accompanied by a sense of unease, worry, and intrusive thoughts that cannot be put to rest. Anxiety disorders are among the most prevalent psychiatric disorders in the United States. Recent surveys estimate the prevalence of anxiety in the general U.S. population ranging from 12.6% to 17.2%. Psychologists have suggested that

clinical and subclinical anxiety are not clearly separable phenomena. As a result, prevalence estimates may be conservative because they fail to include individuals who experience high anxiety levels but who do not meet diagnostic criteria for an anxiety disorder.

A characterization of anxiety can be informed by an understanding of the nature of emotions more generally. Theorists generally agree that specific emotions arise out of the interaction between individuals and their environments, and motivate individuals to respond to external events (Frijda, 1986). For example, if one is crossing a street and sees a car approaching quickly, one might feel fear. The fear might then motivate the individual to run out of the way. Although emotions are generally adaptive processes, they can have adverse consequences when the system is taxed beyond the limits of its capability. For example, when individuals are getting ready to take an exam, they might feel anxious about their performance. This anxiety can motivate them to prepare appropriately for the exam. However, if they feel they cannot ever be prepared or cannot cope with their anxiety, the emotion may no longer be adaptive. In such cases, the anxiety may itself become a problem. A variety of theories have been proposed to explain the development of anxiety and its disorders (Amir & Kozak, 1998).

Because the word *anxiety* represents both a lay construct and a scientific term, precise definitions are needed to facilitate research on the topic. Anxiety is a future-oriented negative emotional state that results from perceptions of threat. It is characterized by a sense that one is unable to predict, control, or obtain desired results in upcoming situations (Barlow, 1988). Most people experience some level of anxiety at different points in their lives. Anxiety may be considered as a *state*, an episodic experience of the emotion brought on by specific situations. Or it may be considered as a *trait*, an enduring temperament, or predisposition to experience the state of anxiety frequently. Thus, someone who is characterized as “anxious” may be a person who frequently experiences states of anxiety in response to many different situations.

Because everyone experiences anxiety from time to time, it is useful to distinguish normal from pathological anxiety. Generally, when anxiety occurs repeatedly at high levels, persists when real threats are minimal, and interferes with routine functioning, it may be considered a clinical or pathological manifestation. A number of clinically defined disorders are

subsumed under the heading of anxiety disorders, for example, panic disorder, social and simple phobias, generalized anxiety disorder, and posttraumatic stress disorder. Psychological research has suggested that pathological and normal anxiety reactions are essentially similar, and differ not in terms of what it means to feel anxious, but in the duration, intensity, and timing of the experience.

## STUDIES OF ANXIETY AND THE HEART

The body’s physiological response mechanisms are well adapted for dealing with short-term physical emergencies such as running from danger. But anxiety and other emotions may activate these same physiological responses in the absence of actual danger. If such responses are turned on frequently, or are not shut off appropriately, they can become damaging. Thus, anxiety may influence heart health directly because it evokes physiological processes (e.g., excessive release of hormones, increased speed of heart rate), and indirectly because it influences health-related behaviors.

Studies have examined the relationship between anxiety and CHD or mortality in a number of different ways. Causality between emotion and health may go in both directions—chronic anxiety may set disease processes in motion, but feeling sick may also make people anxious. Moreover, if chronic anxiety is going to influence health, it will be a function of cumulative effects over time. It is not feasible to conduct true experiments in which people can be assigned to experience anxiety or not on an ongoing basis. As a result, prospective studies are best suited for investigating the risk of disease or death associated with chronic anxiety. These studies measure anxiety among initially disease-free individuals, and follow them over time to see who develops heart disease or dies. This allows investigators to be sure that illness is not causing anxiety.

## Anxiety and Coronary Heart Disease

### *Development*

Most prospective epidemiological studies have found an association between self-reported symptoms of anxiety and risk of developing CHD. In one of the earliest cohort studies, the Northwick Park Heart Study, 1,457 initially healthy men were followed for 10 years (Haines, Imeson, & Meade, 1987).

This study found a significant association between self-reported symptoms of phobic anxiety and fatal CHD. Compared with men reporting low anxiety levels, more anxious men were at almost 4 times the risk of fatal CHD (relative risk = 3.77, 95% confidence interval 1.64 to 8.64). These associations were present after taking account of other coronary risk factors (such as family history of heart disease). Other studies have found similar results using a variety of different measures of anxiety, with anxious individuals at 2.5 to 6 times the risk of CHD compared with less anxious individuals. In most studies, investigators have found a “dose-response” effect such that increases in anxiety were associated with increases in risk of CHD. A strength of these studies is that they all tried to control for numerous confounding factors, such as family history of heart disease or smoking. The magnitude, consistency, and dose-response gradient of the association lend support to the notion that anxiety may contribute to risk of CHD. Nonetheless, more work is needed to examine and confirm the nature of this association.

A small number of studies have not found evidence of anxiety as a risk factor for CHD, although generally the design of these studies was not as strong as the studies with positive findings (Kubzansky, Kawachi, Weiss, & Sparrow, 1998). Some investigators have speculated that the apparent excess risk of CHD among anxiety disorder patients may be due to a drug effect, since many of these patients use psychotropic medication. Little research has been done that directly addresses this question. However, one study of fatal heart attack in women examined the use of antianxiety medication, and found that the excess risk of coronary death was unlikely to be due to the effect of a drug. Rather, this study found that the excess risk of CHD death was related to the underlying condition that led to the original prescription of psychotropic drugs, rather than to the drugs themselves (Thorogood, Cowen, Mann, Murphy, & Vessey, 1992). The possibility that subclinical heart disease may lead to the subjective experience of anxiety cannot be excluded. However, no data presently exist demonstrating a relationship between subclinical CHD and anxiety. In the absence of symptoms, it is difficult to argue that knowledge of potential disease status, or physical discomfort associated with subclinical disease, caused anxiety. In fact, it has been found that individuals reporting symptoms of CHD often have normal or near normal arteries, suggesting that these individuals have primary psychiatric rather than cardiac disorders.

### *Prognosis*

Although researchers have more often studied effects of depression rather than anxiety in coronary patients, a number of studies have found that anxiety is also very common among individuals with established heart disease. Approximately 50% of patients in the coronary care unit exhibit very high levels of anxiety. Unfortunately, in the vast majority of these patients, the anxiety is neither diagnosed nor treated. Studies have suggested that the increased risk of further complications in highly anxious patients with heart disease may range from 2.5- to 5-fold (Moser & Dracup, 1996). As yet, the mechanisms for these effects are not well understood. However, given that anxiety activates a variety of physiological and behavioral responses known to influence heart health, it may affect not only the development of CHD but also outcomes following acute coronary events.

### *Anxiety and Mortality*

Researchers have also studied the association between anxiety and mortality. The majority of published studies have found that there is indeed a relationship between anxiety and mortality—generally, these studies have been methodologically stronger than those that did not find such a relationship. In many of these studies, the cause of death was related to CHD. For example, studies of psychiatric patients have suggested a link between anxiety disorders and premature death from CHD. However, a number of studies have also suggested that anxiety is associated with other causes of death. For example, two recent studies found that among breast cancer patients, those with higher levels of anxiety did not survive as long (Gibrar, 1996; Weihs, Enright, Simmens, & Reiss, 2000). Other studies have found increased risk of premature mortality from all causes of death for highly anxious individuals relative to those who are less anxious. Some of this work has found that men (but not women) with anxiety disorders are at increased risk for premature mortality. However, a systematic comparison of risk for men and women has not yet been done.

### *Potential Mechanisms: Physical Effects of Anxiety*

Several mechanisms have been proposed by which chronic anxiety may result in damage to the heart and subsequent increased risk of CHD. Anxiety may affect

the heart indirectly by influencing a variety of behaviors that can damage the heart over time, including loss of sleep, decreased physical activity, poor diet, and increased smoking, alcohol consumption, and drug use. A variety of research has found that anxious individuals are less likely to engage in health-promoting behaviors (Kubzansky et al., 1998). Anxiety may also trigger cognitive or social processes that, in turn, affect health. For example, anxious individuals may be less likely to have effective problem-solving skills. Thus, they may experience higher levels of stress in response to a variety of situations relative to their less anxious peers.

Chronic anxiety may also cause damage to the heart more directly by repeatedly activating the sympathetic nervous system, causing excess release of hormones, and suppressing immune function (Schneiderman, 1987). This may lead to a cascade of effects beginning with physical and chemical changes in the blood and blood flow that ultimately damage the heart. For example, the recurring release of certain hormones may cause a buildup of fatty deposits in the coronary arteries. This can lead to atherosclerosis—damage in the coronary arteries resulting in narrowing and eventual impairment of blood flow. One recent study found that atherosclerosis developed at a faster rate among individuals reporting high versus low levels of anxiety (Paterniti, Zureik, Ducimetiere, Fève, & Alperovitch, 2001).

Anxiety may also influence the electrical stability of the heart in a variety of ways. Recurrent anxiety may disrupt the balance between the sympathetic and parasympathetic nervous systems that together regulate cardiac rhythm. Heart rate variability (HRV) provides a noninvasive measure of this balance. A variety of studies provide converging evidence of an association between anxiety and altered HRV. In some studies, decreased HRV has been associated with social inhibition in children, itself a developmental precursor of panic and other anxiety disorders. Multiple studies have also revealed an association between anxiety and altered HRV among adults. Taken together, these findings suggest that abnormal regulation of cardiac rhythm, as measured by reduced HRV, may be an important mechanism linking anxiety and CHD, especially sudden cardiac death.

Anxiety may also place people at greater risk for CHD by leading to alterations in blood pressure and heart rate. Generally, the research suggests that a stable anxious disposition is related to an increased risk

of high blood pressure (hypertension). Studies in psychiatric and nonclinical settings largely support the notion that highly anxious individuals are more likely to develop hypertension. For example, one study of 468 middle-aged normotensive women found that those with more anxiety had greater increases in systolic blood pressure over a 3-year period (Markovitz, Matthews, Wing, Kuller, & Meilahn, 1991). Effects of anxiety on blood pressure may be even greater than research has found to date. Some investigators have found that there is a subset of anxious individuals who repress their anxiety, and as a result are not identified as being anxious by the usual measures. However, research designed to identify these people has often found that repressed anxiety is also associated with increased risk for hypertension.

#### *Acute Anxiety and Triggering of CHD*

There is some evidence that anxiety might have immediate effects and actually trigger a heart attack. Triggering mechanisms may differ from those that incur long-term damage. For example, the sharp hemodynamic changes associated with acute anxiety states may precipitate plaque rupture in predisposed coronary vessels. For example, one study found that risk for heart attack was approximately 1.5 times increased when an anxiety episode occurred in the 2 hours preceding the event (Mittleman et al., 1995). Thus, anxiety may influence CHD and mortality via both chronic and acute effects.

## ANXIETY: ITS MEANING AND MEASUREMENT

---

Anxiety emerged as a central problem and a predominant theme of modern life in the 20th century, which the French author Albert Camus referred to as "the century of fear" (May, 1950/1977). The *Age of*

*Anxiety* was the title of both Leonard Bernstein's Second Symphony and a poetic work by W. H. Auden (May, 1950/1977). Inspired by Bernstein's music and Auden's poem, Jerome Robbins choreographed a contemporary ballet, which he also titled the *Age of Anxiety* (Mason, 1954). The significant impact of anxiety in literature, music, art, and religion, as well as in psychoanalysis, psychiatry, and psychology, was cogently described by Rollo May (1950/1977) in his classic book, *The Meaning of Anxiety*. May also documents concern with anxiety in the philosophical work of Pascal, Nietzsche, Schopenhauer, and, especially, Kierkegaard and Spinoza, who considered fear to be a state of mind characterized by the expectation that something painful or unpleasant might happen.

Although the pervasive influence of anxiety on human behavior was not generally recognized until the 20th century, concerns with fear are as old as the history of humankind. The concept of fear was clearly represented in ancient Egyptian hieroglyphics, the Old Testament, and in Greek and Roman literature (May, 1950/1977). The importance of fear was clearly recognized by Charles Darwin (1872/1965), who considered this emotion to be an inherent characteristic that had evolved in both humans and animals as an adaptive response over countless generations. Observable manifestations of fear included: rapid palpitations of the heart, trembling, increased perspiration, changes in voice quality, erection of the hair, and peculiar facial expression. Consistent with contemporary definitions of anxiety, Darwin observed that fear varied in intensity, from mild apprehension or surprise, to an extreme "agony of terror."

The physiological manifestations that Darwin attributed to fear were also recognized as symptoms of anxiety by Sigmund Freud (1933/1959, 1936). However, Freud emphasized the experiential qualities of anxiety, which he defined as "something felt," an unpleasant emotional state characterized by subjective feelings of chronic apprehension, and by "all that is covered by the word 'nervousness'" (1895/1924, p. 79). The perceived presence of danger, according to Freud, evoked an anxiety state that served to warn the individual that some form of adjustment was necessary. Stimulated by psychoanalytic theory, clinical studies of anxiety have been reported in the psychiatric literature with increasing regularity. Pavlov's (1927) discovery of experimental neurosis also stimulated numerous investigations of fear and anxiety in animals. However, prior to 1950, there were relatively

few experimental studies of anxiety in humans. Ethical problems associated with inducing anxiety in the laboratory contributed to this paucity of research, which could not advance beyond a prescientific level until objective and reliable measures of anxiety were available.

The Taylor (1951, 1953) Manifest Anxiety Scale (TMAS) was the first of a number of widely used psychometric instruments designed to assess anxiety in adults. The rationale for constructing the TMAS, which has been used extensively in research on motivation and learning (Spence & Spence, 1966), was based on the assumption that anxious people are chronically more emotional and consistently higher in motivation or drive level than persons low in anxiety. The 50 TMAS items were selected from the Minnesota Multiphasic Personality Inventory (Hathaway & McKinley, 1942, 1951) on the basis of a textbook description of the symptoms observed in patients with anxiety neurosis (Cameron, 1947), a clinical syndrome first identified by Freud (1895/1924). Respondents to the TMAS report whether or not each item describes how they generally feel.

The TMAS, Cattell's (1957) Anxiety Scale Questionnaire (ASQ; Cattell & Scheier, 1963), the Affect Adjective Check List (AACL; Zuckerman, 1960; Zuckerman & Lubin, 1965), and the State-Trait Anxiety Inventory (STAI; Spielberger, 1983; Spielberger, Gorsuch, & Lushene, 1970) are the psychometric instruments that have been most frequently used to assess anxiety in research and clinical practice over the past 50 years. Cattell and his colleagues (Cattell, 1966; Cattell & Scheier, 1958, 1963) pioneered the use of multivariate techniques in the assessment of anxiety, and identified trait and state anxiety as unique constructs. As currently defined (Spielberger, 1966, 1972a), trait anxiety (T-Anxiety) refers to relatively stable individual differences in anxiety proneness as a personality trait or disposition, whereas state anxiety (S-Anxiety) is defined as a transitory emotional condition that varies in intensity and fluctuates over time. The 40-item Anxiety Scale Questionnaire (ASQ) developed by Cattell and Scheier (1963) provides an objective measure of individual differences in trait anxiety, and is highly correlated with the TMAS. The IPAT 8-Parallel Form Anxiety scale was developed to assess S-Anxiety by Scheier and Cattell (1960), but there is little evidence of the construct validity of this measure.

The AACL developed by Zuckerman (1960), with adjectives that describe the presence or absence of anxious feelings, assesses both state and trait anxiety. Respondents check each of the 21 AACL adjectives to indicate *how they feel on the day the test is given* (S-Anxiety), and then check these same adjectives to indicate *how they generally feel* (T-Anxiety). The concepts of state and trait anxiety, as refined and elaborated by Spielberger (1966, 1972a, 1972b, 1977, 1979), provided the conceptual framework for constructing the STAI, which was intended to provide reliable, relatively brief, self-report scales for assessing state and trait anxiety in research and clinical practice (Spielberger et al., 1970).

In developing the STAI, the initial goal was to identify a single set of items that could be administered with different instructions to assess the intensity of S-Anxiety and individual differences in T-Anxiety. Items adapted from existing anxiety measures, along with a number of new items, were administered, first with state and then with trait instructions, to large samples of university students and psychiatric patients. Based on extensive item-validity research with more than 2,000 study participants, 20 items were selected for the preliminary form of the STAI. However, subsequent research indicated that altering the instructions could not overcome the strong state or trait psycholinguistic connotations of the key words in a number of items (Spielberger et al., 1970). (For example, "I worry too much" was stable over time and correlated highly with other T-Anxiety items, but scores on this item did not increase in response to stressful circumstances, nor did they decrease under relaxed conditions, as required for the construct validity of an S-Anxiety item. In contrast, "I feel upset" was a highly sensitive measure of S-Anxiety; item scores increased markedly under stressful conditions and were lower under relaxed conditions. However, when given with trait instructions, the scores for this item were unstable over time and correlations with other T-Anxiety items were relatively low.)

Given the difficulties encountered in measuring state and trait anxiety with the same items, the best items for assessing S-Anxiety and T-Anxiety were selected for the STAI (Form X). When given with trait instructions, the 20 items with the best concurrent validity, as indicated by the highest correlations with the TMAS and the ASQ, and that were stable over time, were selected for the T-Anxiety scale (Spielberger et al., 1970). The 20 items with the best construct validity when given with state instructions,

as indicated, respectively, by higher and lower scores under stressful and nonstressful conditions, were selected for the S-Anxiety Scale. Only 5 of the 20 items met the validity criteria for both scales. The remaining 15 items were relatively unique measures of either state or trait anxiety. Further insights gained in more than a decade of research, which contributed to clearer conceptual definitions of the concepts of state and trait anxiety, stimulated a major revision of the STAI. The item selection and validation procedures that guided the replacement of 30% of the original items are described in detail in the revised STAI (Form Y) Test Manual (Spielberger, 1983).

In the construction and standardization of the STAI (Form Y), more than 5,000 additional subjects were tested. Factor analyses of the Form Y items identified distinct state and trait anxiety factors (Spielberger, Vagg, Barker, Donham, & Westberry, 1980), which were similar to those found in previous factor studies of the Form X items (Gaudry, Spielberger, & Vagg, 1975). However, the Form Y factors were more differentiated and had better simple structure than the corresponding Form X factors, reflecting "purer" measures for assessing state and trait anxiety in adolescents and adults, and a better balance in the number of T-Anxiety present and absent items (Spielberger et al., 1980). Since the STAI was first published more than 30 years ago (Spielberger et al., 1970), this inventory has been translated and adapted in 62 languages and dialects, and cited in more than 14,000 archival studies.

## APPLIED BEHAVIOR ANALYSIS

---

*Applied behavior analysis* is the science in which procedures derived from the principles of learning are systematically applied to address problems of social significance. Burrhus F. (B. F.) Skinner, for many years a professor at Harvard University and, arguably, the most famous psychologist of the 20th century, studied learning processes in both laboratory animals and humans, carefully delineating a behavioral principle known as operant conditioning. Operant conditioning, the central principle of applied behavior analysis, refers to a process in which the future probability of a behavior is powerfully controlled by both its positive and negative consequences. In 1968, the

growing relevance of this approach to addressing social problems was recognized with the publication of the first issue of the *Journal of Applied Behavior Analysis* and, subsequently, further extended in 1999 to community venues with the publication of the first issue of the *Journal of Positive Behavior Interventions*. The approach has been used with both children and adults in settings related to education, the community, the workplace, the family, and, of particular relevance, health.

## BASIC CONCEPTS

The key concept in understanding operant conditioning is that of the three-term contingency, referring to a sequence of events that consists of antecedent discriminative stimuli ("trigger" stimuli), behavior, and consequences. Operant behavior is influenced by the temporal and functional relationships it has with its antecedents and consequences. In illustration, consider a child whose parent presents a request ("Please put away your toys."). The child may respond with either of two behaviors: compliance or tantrums, depending on the consequences that have followed these behaviors in the past. Some consequences for compliance, for example, parental praise, may have the effect of increasing the future rate of the behavior. When a behavior is followed by the *presentation* of an event (in this case, praise) that increases the future rate of the behavior, the consequence is referred to as a positive reinforcer. The future rate of a behavior can also be increased by *removing* an event following a particular behavior in which case the consequence is referred to as a negative reinforcer. For example, if the parent responds to the child's tantrums by no longer insisting that the toys be put away, the child may become more likely in the future to respond to such requests by throwing a tantrum. In this case, removal of the request to put the toys away functions as a negative reinforcer for tantrums.

Other consequences function to decrease the future rate of behavior. These are referred to as punishers. For example, the parent may *present* an event such as a loud reprimand whenever the child throws a tantrum. The effect, at least in the short term, may be a cessation of the tantrum. In this case, the reprimand functions as a punisher. The future rate of a behavior can also be decreased by *removing* an event following display of the behavior. For example, the parent may send the child to his or her bedroom following

the display of tantrums. This procedure, technically known as timeout, may produce a decrease in the future rate of tantrums. In timeout, punishment involves the removal of many potential positive reinforcers; that is, while the child is sitting in the bedroom, there is no possibility of playing with toys, watching television, or socializing with parents, the absence of which constitutes an aversive (punishing) consequence for tantrums.

Finally, antecedent stimuli also influence operant behavior through their association with past consequences. In illustration, using the previous example, if a mother responds to her child's tantrums by withdrawing her request to put away the toys but the father responds by sending the child to timeout, then the child is likely in the future to display tantrums when the mother makes the request and compliance when the father does so. Technically, this outcome illustrates the phenomenon of stimulus control in which different antecedent stimuli (i.e., requests from mother vs. requests from father) are associated with different rates and types of operant behavior because of differing histories of consequences associated with each of the antecedent stimuli.

The basic concepts just described have been used to achieve a variety of goals relevant to health issues, especially with children. In what follows, several generic goals pertinent to these issues are presented with illustrative examples.

### FACILITATING MEDICAL DIAGNOSIS

Operant conditioning has been used to ensure patient cooperation during complex diagnostic procedures. An example involves magnetic resonance imaging (MRI) for very young children. Keith Slifer and his colleagues at Johns Hopkins University School of Medicine worked with four children, ages 5-6 years. Typically, children this young are sedated prior to MRI scans because the accuracy of such scans depends on the patient remaining still for 20 minutes or more, a difficult task for young children. Also, the scanners are quite noisy and may engender fear, further reducing cooperation. Although sedation can overcome these difficulties, it can also produce undesirable side effects such as respiratory depression. Therefore, as an alternative to sedation, Slifer and colleagues incorporated an operant conditioning component into the diagnostic procedure. Specifically, they altered the MRI environment so that the child could

view an interesting cartoon while lying in the machine. Viewing the cartoon videotape was contingent on body movements of 2 mm per second or less; anything greater than that caused the cartoon to stop for 3 seconds. Thus, lying still was positively reinforced. Furthermore, the more times the children met the criterion, the more treats and prizes they earned later. This reinforcer package produced very low rates of movement, compatible with accurate imaging. Although research is needed to determine whether these procedures are equally applicable to elective versus emergency MRI scans, they appear to offer practitioners a potential alternative to sedation that is developmentally appropriate as well as increasing patient comfort and compliance.

### ADHERENCE TO MEDICAL REGIMENS

The fact that an individual has been prescribed an effective drug for a medical condition is no guarantee that the individual will faithfully adhere to the prescribed course of treatment. In the case of a serious illness such as asthma, this lack of adherence could have fatal consequences. Irene da Costa and her colleagues at the University of Kansas Medical Center worked with two asthmatic children, 8 and 10 years of age, who were referred by an allergist for poor adherence to a medical regimen that consisted of inhaling the drug beclomethasone several times a day. Adherence was assessed with an electronic monitor, attached to the inhaler, that recorded and stored the date and time of each inhaler actuation.

To motivate the children, the investigators used a token system, the technical term for a reinforcement approach that, in the present case, involved the children earning points for taking medication, and losing privileges for not doing so. When sufficient points had been accumulated, the children could exchange them for a variety of special privileges. The points and back-up privileges thus served as reinforcers for compliance, and the loss of privileges, as punishers for lack of compliance. Over a period of several weeks, during which the token system was evaluated, adherence rose to high levels. In all likelihood, additional procedures would be needed to produce long-term impact on behavior and health. However, many medical conditions require only short-term management and, therefore, reinforcement approaches may offer promise as a strategy for promoting adherence.

## ADJUNCT TO MEDICAL INTERVENTION

During the course of medical intervention, problems sometimes arise that are not resolved solely by the use of the intervention itself. In these instances, operant conditioning procedures can prove to be a useful adjunctive treatment. An example comes from a study of pediatric burn victims carried out by Mary Lou Kelley and her colleagues at the University of Mississippi Medical Center. Two girls, 4 and 6 years of age, were receiving hydrotherapy for extensive body burns. This medical intervention involves sitting in a whirlpool tub after which dead skin is removed and dressings are applied. The procedure was aversive to the children, producing verbal pain (e.g., screaming), motoric pain (e.g., flailing, aggression), high levels of fear, and low levels of cooperation.

A procedure was designed whereby the children were encouraged to watch amusing cartoons during hydrotherapy and told it would help them to “forget” about their pain and make the time go faster. The children were also told that they could place a “star” (reinforcer) on a chart for every session that an adult judged their “pain” behavior to be less than they had shown prior to the cartoon/star intervention. This strategy produced a decrease in both verbal and motoric pain behavior, measured directly. In addition, the children’s mothers and physical therapists rated the children as showing lower levels of pain and fear as well as higher levels of cooperation. Using the terminology described earlier, the cartoons likely functioned as discriminative stimuli for socially appropriate behavior, and stars as reinforcers for the occurrence of behaviors that expressed diminished levels of pain. While these operant procedures were unlikely to have reduced the subjective experience of pain, they had a desirable impact on the negative behavioral and affective sequelae associated with an unpleasant medical intervention.

## REDUCING UNHEALTHY BEHAVIOR PATTERNS

During the course of their lives, many people learn behavior patterns that ultimately produce negative health consequences. A good example concerns poor eating habits that result in obesity, a widespread problem correlated with heart disease, cancer, and other serious illnesses. Typically, obesity is dealt with through a combination of diet and exercise programs. However, Richard Stuart, formerly of the University of

Michigan at Ann Arbor, proposed that the impact of these programs could be enhanced by the additional use of operant conditioning principles to alter unhealthful eating patterns. Stuart’s suggestions are often incorporated into obesity management programs for both children and adults, and have been shown to contribute to controlling weight in the short and long term.

One strategy, defined earlier, involves stimulus control. Specifically, individuals are taught to eliminate discriminative stimuli that trigger poor eating, for example, by removing junk foods from the house, by immediately throwing meal leftovers into the garbage rather than having them available for subsequent snacking, by food shopping only after consuming a full meal to avoid hunger-driven impulsive eating in the store, and by eating in one room only to ensure that multiple sites do not become associated with and, therefore, trigger eating episodes. Also, alternatives to unhealthful eating patterns are positively reinforced. That is, arrangements are made with family members and friends to ensure that they recognize and praise the person as weight is lost (“You look 10 years younger!”). When weight goals are met, material consequences are programmed. For example, the person now purchases elegant clothing appropriate for a “slim” person or goes on a special vacation as a reward. In sum, by focusing on changing the antecedents and consequences for eating behavior rather than focusing exclusively on weight loss, one teaches individuals long-term strategies for controlling their unhealthful eating patterns, thereby potentially contributing to future health.

## MOTIVATING HEALTHY BEHAVIOR

The principles of applied behavior analysis have also been used to motivate healthy behavior. For example, rather than waiting until children become obese before acting, some investigators have tried to prevent such problems by intervening early. Lori Stark and her colleagues at the Brown University Medical School worked with preschool children who had, as yet, no weight problems. They offered these children a variety of snacks, some healthy (e.g., fruits and vegetables), some unhealthy (e.g., chips and cookies). When a child selected a healthy food to eat, he or she received positive reinforcement in the form of teacher praise as well as preferred colorful stickers (e.g., those depicting rainbows, hearts, cars). Unhealthy choices received negative feedback (i.e., feedback that educated the child regarding healthy versus unhealthy foods; for example,

“You picked a cookie. Cookies aren’t as good for you as fruits or vegetables.”). In addition, the children were taught to solicit teacher praise following a healthy choice (e.g., “I picked a good snack, didn’t I?”).

This program was in effect during the school year and was also extended to the home. The outcome was that the children reliably selected healthy foods at a high rate that far exceeded the rate of such choices before the program was implemented. Given these positive results, a clear priority would be to follow up this study to determine the long-term health benefits of such an intervention. At a minimum, however, the study demonstrates the potential utility of operant conditioning strategies for promoting the early development of good nutritional practices.

In sum, applied behavior analysis has proven useful in helping to address a number of generic issues of importance in the field of health, including facilitation of medical diagnosis, adherence to medical regimens, adjunctive medical intervention, reducing unhealthy behavior, and motivating healthy behavior as a strategy for the prevention of future illness.

## ARTHRITIS: BEHAVIORAL TREATMENT

---

Arthritis refers to a group of more than 100 disorders in which the joints become damaged, often as a result of inflammation. There is no known cure for arthritis and as such, it is a common condition that is usually chronic in nature and causes significant pain and disability. Although disability in arthritis is associated with damage to the joints that can be identified through examinations (such as X-rays), damage does not entirely predict the level of function that individuals achieve. Indeed, it has long been recognized that psychological factors, such as attitudes toward illness, coping styles, depression, and anxiety are also important predictors of function over time.

One model that has been adapted to explain the process of adjustment to arthritis is the self-regulation model. According to this model, people have beliefs about arthritis prior to being diagnosed. These beliefs influence the way in which people cope with the illness. For example, if people believe that arthritis is a serious condition, which is likely to be chronic and disabling and over which they have no control, they may be inclined to do little to actively cope with the illness and instead rest. When they rest, the acute pain improves and hence they appraise the coping strategy of resting as helpful, increasing its use. In addition, there is also an emotional response to the symptoms, such as fear or anxiety. People with arthritis will then attempt to cope with these negative emotions, such as through avoidance of activity. Again, avoidance will lead to an immediate reduction in anxiety, promoting its use as a coping strategy in the future.

The importance of attitudes, coping, and subsequent behavior in response to illness has led to the development of psychological treatments for arthritis. On the basis of models that emphasize the role of attitudes and behaviors, the most commonly evaluated of the psychological treatments is known as behavioral or cognitive-behavioral treatment or therapy (CBT). Cognitive-behavioral treatments refer to interventions that aim to help people to change their behavior and/or attitudes toward the illness in a way

that will facilitate physical and psychological adjustment to their symptoms. CBT interventions commonly use a range of different strategies with the aim of helping patients to self-manage their symptoms. Although most of the research has been conducted with patients with rheumatoid arthritis, it is likely that these approaches would also be helpful to people with related disorders, such as systemic lupus erythematosus, ankylosing spondylitis, or Sjogren's syndrome.

## BEHAVIORAL THERAPY

There are two very different approaches that constitute behavioral treatments: operant programs and self-management.

### Operant Programs

Operant programs are based on the principles of operant conditioning. That is, behaviors are learned according to whether rewards or punishment follow the performance of those behaviors. For example, if a person with arthritis is in pain and engages in a pain behavior (e.g., grimacing or holding painful areas), relatives may realize that the person is in considerable pain and give the person extra attention (positive reinforcement) or take over his or her duties (negative reinforcement). These responses to the pain behavior will result in the person learning to express his or her pain through performing various behaviors that indicate that the person is in pain.

The early behavioral approaches to chronic pain management used operant approaches to reduce the performance of pain behaviors and to reduce downtime (i.e., the time that people spend resting). Operant approaches train the family members of people in pain to give attention and other rewards to "well" behaviors, while ignoring times that the person with arthritis engages in pain behavior. As a result, people with arthritis are encouraged to increase their activity and appropriate communication about pain, while reducing their reliance on pain behaviors and rest. Although operant programs were popular early in the development of behavior therapy for chronic pain patients, they have rarely been applied specifically to people with arthritis. More popular in recent decades have been behavioral approaches that encourage people with arthritis to actively manage their symptoms appropriately.

### Self-Management Approaches

Self-management approaches are largely based on stress and/or pain management principles. The behavioral strategies aim to help people with arthritis change their behavior in a way that will allow them to better manage their symptoms. This includes encouraging people to achieve an optimal balance between rest and exercise, learning to relax, manage stress more effectively, and communicate with others in asking for help, when required. The most commonly employed strategies are activity pacing and goal setting, problem solving, relaxation and/or biofeedback, and assertiveness and communication. Most commonly, behavioral treatments involve some combination of these different strategies.

#### *Pacing and Goal Setting*

It is increasingly recognized that it is important for people with arthritis to maintain a balance between rest and exercise. In arthritis, excessive rest typically results in the joints becoming stiff; that, in turn, leads to a reduction in the person's function. On the other hand, excessive activity on inflamed joints (such as in rheumatoid arthritis) can be damaging and lead to increased disability. Hence, it is important for people with arthritis to learn to balance rest and exercise by pacing their activities across the days and weeks and setting realistic goals. Given that most forms of arthritis are marked by their unpredictability, an appropriate balance of activity can be difficult to achieve. People with arthritis often develop bad habits of overdoing things when they feel well (in case tomorrow is a bad day), only to find that their activity leads to a flare-up in symptoms requiring them to rest the following day.

#### *Problem Solving*

Arthritis creates a range of problems in people's lives from how to manage particular tasks (such as turning on taps) to work and finance-related issues. Problem solving typically makes a number of stages of the process of solving problems explicit. These include brainstorming possible solutions, reviewing the consequences of those solutions, choosing a course of action, and implementing the most helpful solution. For people with arthritis, problem solving can be helpfully applied to the activities of daily living that become problematic as a result of limitations to function.

### *Relaxation and Biofeedback-Based Strategies*

Most behavioral self-management programs include a component that teaches people relaxation strategies. Relaxation exercises often consist of progressive muscular relaxation where people with arthritis are taught to tense and relax different muscle groups throughout the body. However, other programs include similar relaxation exercises without tension cycles and with the use of imagery to facilitate relaxation. In the 1980s, it was common for biofeedback, the provision of information about a particular aspect of the body's functioning, to be used to assist people with arthritis in achieving relaxation. Although less popular in recent years, many of the behavioral programs that have been evaluated have included biofeedback.

In the arthritis literature, two types of biofeedback have commonly been employed: thermal biofeedback and muscle biofeedback (electromyography) or EMG biofeedback. Thermal biofeedback gives people immediate feedback of their body temperature, and its application to arthritis is based on the assumption that there are problems with circulation in patients with some forms of arthritis, such as rheumatoid arthritis. People with rheumatoid arthritis would be attached to a biofeedback machine, usually to a finger, which would provide information about the skin temperature. People are then encouraged to use a range of relaxation or imagery techniques in order to warm that area. Research shows that people can learn to gain better control over their skin temperature, although it is unclear whether this translates to clinical benefits. EMG or muscle biofeedback works on a similar principle, but gives feedback about the level of muscle tension in a particular muscle group of the body. The application of EMG biofeedback is based on the pain-tension-pain cycle. That is, when individuals are in pain, they are likely to tense their muscles as a reaction to the pain (or in anticipation of pain) and this tension, in turn, exacerbates the pain. Hence, it is argued that EMG biofeedback can facilitate people's acquisition of relaxation skills by providing immediate feedback about the level of muscle tension in a particular region. Furthermore, with EMG biofeedback, people with arthritis can be taught to apply relaxation strategies to stressful situations and/or activities that they need to complete.

### *Assertiveness and Communication*

Arthritis almost inevitably affects a person's level of function in some way. As a result, role expectations

change. People themselves can find it difficult to accept these changes in role functions, but changes in expectations also have an impact on those around the individual, including their families, friends, and coworkers. People with arthritis can find it difficult to communicate about their needs in a helpful way and yet such communication is very important. This is particularly so early in the course of the disease. For example, the literature suggests that a large proportion of people who develop rheumatoid arthritis will lose their employment within the first 2 years of illness and that employment status is an important predictor of long-term outcome. Therefore, helping people to communicate assertively with their employers about the impact of their illness on their work is essential in trying to maintain employment, where appropriate.

In teaching patients about communication, the differences between behaving in a passive, assertive, or aggressive manner are usually described or demonstrated. Examples are usually taken from people's lives, and role-plays can be used where people with arthritis can practice different ways of communicating. A focus is not only on the nature of the verbal content of communication but also on the nonverbal signals that accompany the person's message. While many people with arthritis will have good communication skills, they often have some reticence in behaving assertively in various situations that they encounter. Common situations that people identify as needing assertive skills include talking with doctors and asking for help from other people. The aim of assertiveness is to help people understand their rights in various situations and balance their rights with those of other people, allowing open communication between the parties to occur.

### COGNITIVE THERAPY

Cognitive therapy was initially developed for the treatment of depression, and it is a well-established and effective treatment for mood disorders. Symptoms of depression are more common in individuals with chronic illness than in the general population, and this includes patients with arthritis. Hence, cognitive strategies are likely to be helpful to those individuals who are depressed as a result of their illness or its limitations. However, cognitive therapy also has an important role more generally in helping people cope with arthritis. Attitudes toward illness are associated with adjustment. For example, those

people with arthritis who believe that the illness is uncontrollable have been shown to have much poorer adjustment to illness than those who believe that they can control their symptoms. As a result of findings that emphasize the importance of attitudes toward illness, cognitive strategies are frequently employed in behavioral self-management approaches to facilitate the effectiveness of the behavioral components of treatment.

For example, assertiveness skills can be practiced from a behavioral point of view through practicing the verbal and nonverbal behaviors that correspond to assertive communication; however, some people with arthritis hold views that prevent them from using these skills, such as worrying that they are a burden to others or not wanting to question their doctor. The attitudes that prevent individuals from behaving assertively can be addressed through using cognitive strategies, such as cognitive restructuring. Similar attitudes can prevent individuals from using other behavioral strategies. For example, individuals who believe that they should be able to maintain a high level of function, despite their arthritis, find pacing particularly problematic and may be at risk of becoming overactive.

### Attention Diversion

One of the most common symptoms of arthritis is joint pain. Pain interferes with an individual's ability to concentrate on tasks because it is difficult to remove attention away from the source of the pain. As the pain becomes more severe and more chronic, the degree to which people can ignore the pain reduces further. Research has found that the way in which individuals with arthritis cope with the pain predicts the amount of pain that they experience. Hence, teaching patients coping strategies for dealing with the pain and being able to keep their attention on other factors is a helpful part of psychological treatment.

Many people with arthritis develop very helpful ways of dealing with their pain independently, and the aim of attention diversion strategies is to build further on these helpful resources. People are taught to use nondemanding physical activities and mental strategies to take their mind off the pain. Typically, these are helpful in managing mild to moderate levels of pain. Some people with arthritis find the use of imagery directed toward the pain very helpful in dealing with more severe levels of pain. For example,

those who feel that their pain is like burning can use imagery to imagine the pain becoming cooler and cooler. As people develop individual images and practice these, such cognitive strategies can be very helpful for managing more severe levels of pain and allowing people with arthritis to use more traditional attention diversion strategies, such as engaging in a nondemanding activity or mental activity.

### Cognitive Challenging

The cornerstone of cognitive therapy relies on cognitive restructuring. People with arthritis are helped to understand the relationship between situations that arise, the meaning of those situations, and the emotions that they experience. For example, if a person with arthritis drops a cup and breaks it due to weakness in their hands, it is not the broken cup that is usually associated with feeling upset. Rather, dropping the cup is sometimes interpreted as meaning that the person is no longer able to cope with daily life or is becoming weak or disabled. Through keeping a record of their thoughts, people can become aware of these automatic thoughts that are unhelpful and contribute to levels of distress. Cognitive therapy allows people with arthritis to learn ways to question these unhelpful thoughts. Furthermore, underlying attitudes or fears about arthritis can be identified and challenged. Many people fear that they will end up in a wheelchair or become a burden to their family. Such beliefs are often unlikely particularly since new treatment approaches have improved outcome for people with arthritis. Challenging unhelpful beliefs such as these can often improve the emotional well-being of people with arthritis.

## OTHER STRATEGIES

### Education About Arthritis

Psychoeducational programs about arthritis are often available, many of them based on the work of Kate Lorig and James F. Fries and *The Arthritis Helpbook* (1990), which provides excellent information for people with arthritis. Education, while not itself a behavioral strategy as such, is frequently included in behavioral or cognitive-behavioral interventions. Research suggests that education about arthritis does improve people's knowledge about the disease and also their self-efficacy (i.e., their confidence that they can manage the illness and its

symptoms). However, education alone is often not sufficient to induce behavioral change. Nonetheless, education does seem necessary to help people understand their illness and the symptoms and is a good basis from which to add further cognitive and/or behavioral skills.

### Stress Management

Stress management is a generic term for a set of cognitive and/or behavioral strategies to help individuals better manage stress. In terms of the strategies that form the basis of stress management, they are largely indistinguishable from those listed above. The difference between stress management and pain management is largely in the focus on managing either pain or stress—the approach is otherwise the same. Stress management is often applied to chronically painful conditions, such as arthritis, on the assumption that the condition increases stress, which, in turn, exacerbates the illness.

### Supportive Counseling

Supportive counseling or psychotherapy refers to providing support and empathy to people with arthritis, without specifically including any skills or strategies. All cognitive and behavioral therapies should be administered within a supportive and collaborative therapist-client relationship. The major difference between supportive counseling and cognitive or behavioral therapies parallels the respective aims of these treatments. The primary aim of supportive counseling is to provide a person with arthritis with support in a nonjudgmental relationship, whereas the primary aim of behavioral therapies is to change people's behavior and of cognitive therapies is to change their attitudes.

### MODE OF TREATMENT ADMINISTRATION

Cognitive and behavioral therapies are most commonly administered in either a group or individual setting. The advantage of individual treatment is that interventions can be individualized to meet the needs of a particular person with arthritis. Since the outcome of people with arthritis varies enormously so too do their needs. Group treatment, on the other hand, has the benefit of people with arthritis meeting one another, which can provide increased support and can

help to normalize people's experiences. It is important that groups are composed of people with similar disease severity to ensure that those people who are less affected by arthritis or are early in the disease process do not become overly concerned about the possibility of deformity and disability that they observe among other group participants.

Self-help educational material is also available, but it is unclear whether cognitive and behavioral skills can be well learned through self-administration. Self-administered pain management has been found to be as effective as individually administered treatment for those people with chronic pain problems who complete a specified manual, but many people fail to complete and the outcome for those people is unknown. Research with people with arthritis has shown that keeping a daily diary of stressful experiences can be effective in improving outcomes for people with rheumatoid arthritis, and so it is possible that self-administered interventions may have value for people with arthritis.

### EFFECTIVENESS OF TREATMENT

There are more than 60 controlled clinical trials of psychological or behavioral interventions in comparison to either standard care or another treatment for people with rheumatoid arthritis alone. Astin, Beckner, Soeken, Hochberg, and Berman (2002) recently conducted an analysis of all the trials that met criteria for being methodologically rigorous. They identified 25 high-quality trials, the majority of which included some cognitive and/or behavioral strategies. Their results suggest that across all the published research of good quality, psychological treatments effectively reduce pain and improve disability, joint function, coping, depression, and self-efficacy immediately following treatment. In the longer term, people with rheumatoid arthritis appear to continue to improve over time with regard to psychological functioning, joint function, and coping, although their pain and disability return to previous levels. In all of the studies reviewed, people with rheumatoid arthritis were not chosen on the basis that they were having difficulty coping or had psychological problems, *per se*. Hence, these results suggest that for people with rheumatoid arthritis, cognitive and/or behavioral treatments can be helpful in addition to medical care.

Similar results have also been shown for people with osteoarthritis, where studies that have been conducted

largely suggest that cognitive and/or behavioral treatments are likely to be helpful as an adjunct to medical treatment. Although other less common forms of arthritis have rarely been the subject of controlled studies, there is no reason to think that similar approaches to treatment would not be equally effective.

### WHO BENEFITS FROM TREATMENT?

Although the effectiveness of CBT for people with rheumatoid arthritis and osteoarthritis seems likely, little is known about which people with arthritis will benefit most from behavioral treatments. People with arthritis who are severely affected and have high levels of disability that have been progressing over the course of the illness do most poorly. Moreover, cognitive-behavioral treatment has been used for people who have been diagnosed with rheumatoid arthritis more recently. Indeed, results are more positive in trials where the illness duration is shorter and those studies that have followed up people with arthritis over time have found that treatment benefits are largely maintained and in some cases further improvements emerge over time. If treatments are effective in people recently diagnosed with arthritis and improvements are maintained, then early administration of treatment can prevent deterioration in disability and the development of psychological problems in reaction to the illness. Hence, it seems likely that the earlier in the course of the arthritis that a person is offered behavioral treatment the more effective treatment is likely to be.

### HOW DO THE TREATMENTS WORK?

The question of how behavioral treatments work is difficult to answer. The question is complicated by the fact that most research has included a number of different cognitive and/or behavioral strategies. As a result, whether there is one particular strategy that accounts for the observed changes in people with arthritis or whether a combination of strategies work together to produce change is unclear. For example, it may be that teaching people with arthritis ways to pace their activity is necessary and sufficient for change. Alternately, it may be that pacing activity is necessary, but not sufficient. Rather, people with arthritis may need to change the attitudes that prevent them from being too active or not active enough in order to make the necessary behavioral changes. At

present, we do not know which strategies are most important or effective.

Although there is no clear answer to which treatment components are effective by themselves or in combination, there is some indication about what possible factors may produce change. For example, many of the studies have investigated disease variables and few of the studies have been able to produce changes in the actual progression of disease for people with arthritis. Therefore, it seems unlikely that the interventions are successful through improving the biological markers of disease (such as acute inflammation in rheumatoid arthritis). Nonetheless, people with arthritis who complete behavioral treatments do improve with regard to joint function.

One factor that has been consistently observed to predict treatment-related changes has been self-efficacy. That is, people with arthritis who become more confident in their ability to manage the disease and its symptoms appear to be those who make the largest improvements. It may be that as people gain increased confidence their mood improves and they subsequently engage in more helpful behaviors relating to their arthritis, such as balancing rest and exercise more appropriately. This interpretation would be consistent with biopsychosocial models of arthritis, but it remains speculative. The precise mechanisms through which cognitive and behavioral treatments work have yet to be clearly identified.

## ARTHRITIS: PSYCHOSOCIAL ASPECTS

---

Within the past century, scientific and medical advancements have been successful in preserving physical health and preventing and treating acute, infectious diseases (e.g., polio, tuberculosis) that negatively affected population health. These accomplishments, coupled with growth in the size and longevity of the older population, have shifted the attention of medical and public health professionals to the prevalence and incidence of chronic medical conditions (e.g., hypertension, arthritis). Research and clinical treatment now focus more specifically on the means to prevent and treat these conditions and to ameliorate their potential harmful impact on physical health and psychological functioning.

Arthritis is one of the most common nonfatal chronic diseases in the United States, and it is the leading cause of pain and physical disability, particularly among adults 65 years of age and older. Derived from the Greek words *arthron* (joints) and *itis* (inflammation), arthritis is a general term used to describe more than 100 different conditions that affect the joints and/or connective tissues (e.g., muscles, tendons). The most common of the arthritis conditions are *osteoarthritis*, which is a musculoskeletal disease

that causes deterioration of the cartilage, and *rheumatoid arthritis*, an autoimmune disease that causes inflammation of the joint lining.

A number of psychosocial factors have been associated with arthritis and have a major impact on the experience of the disease. Psychosocial factors are defined as psychological, behavioral, and social processes that include beliefs, values, perceptions, culture, coping behaviors, personality indicators, and social resources and networks (e.g., social support), all of which can influence how the individual detects, interprets, and responds to the arthritis condition. Sociodemographic factors such as age and gender are also associated with variability in arthritis conditions. For example, certain age cohorts are more likely to develop specific types of arthritis conditions compared to other age groups (i.e., women 65 years of age and older are more likely to experience osteoarthritis compared to women 35 years of age and younger). Psychosocial factors account for significant variation in the physical and behavioral manifestations associated with arthritis and affect the severity and course of the medical condition. Although there are a myriad of psychosocial factors that can influence the outcome of having an arthritis condition, this entry will focus on two indicators (i.e., pain, depression) that are pertinent to physical ability and functional limitations.

## PAIN, CULTURE, AND ARTHRITIS

*Pain* is defined as an unpleasant sensory and emotional experience that affects an individual's physical and psychological health and social well-being. Pain is the cardinal manifestation of an arthritis condition and is often chronic (lasts for an indefinite amount of time), severe, and unpredictable. The experience of pain not only is a major health concern for individuals with arthritis but is a significant predictor of current and future medication use, future pain experiences, and subsequent physical disability.

The intensity of the pain associated with arthritis may result from physiological changes such as joint damage, tissue inflammation, excessive tension and swelling within the joint capsule, and physical activity. The pain experience varies from patient to patient and is contingent on a myriad of factors including the history of the illness, the duration of the medical condition, type (acute vs. chronic) and location of the pain, variability of daily pain and the number of painful days, number of joints affected, physiological

changes (e.g., changes to the body's tissue structure), side effects of medications, and the racial and ethnic (cultural) background of the affected individual.

Although the biological sensations of pain are universal, the meaning, attitudes, and responses to the pain experience differ across racial and ethnic groups. Many racial and ethnic groups have specific "pain rituals" that shape an individual's expectations and beliefs about pain, as well as strategies to tolerate the pain experience. For example, differences in language, ways of understanding and expressing health and disease, the expression and the meaning of pain; preferred modalities of health care management and treatment; and the use of specific strategies to cope with pain are among the many factors that comprise the experience and cultural context of pain.

### PHYSICAL DISABILITY AND ARTHRITIS

In the United States, arthritis is the primary cause of the inability to perform various routine tasks (e.g., personal care, household, work related) and leisure activities. Approximately 3% of the U.S. population report that arthritis significantly impairs their ability to perform certain physical activities such as walking, bathing, and dressing (Centers for Disease Control and Prevention, 1994). Many individuals spend a quarter of their lives in a state of physical disability, infirmity, and/or injury. These circumstances are significantly associated with primary care physician utilization, hospitalizations, increased nursing home admissions, and mortality. The physical limitations associated with arthritis involve a process in which muscle weakness leads to unstable joints; the resulting stress that is exerted on unstable joints causes pain and disability. Paradoxically, attempts to avoid the pain associated with normal activities may lead to increased muscle weakness, which initiates a cycle of activity avoidance, pain, and physical disability.

### ARTHRITIS AND DEPRESSION

Depression is a common clinical disorder for both acute and chronically ill patients. Approximately one third of all patients with a chronic medical condition experience increased rates of depressive symptomatology. Depression is considered the most psychologically debilitating outcome of arthritis. Existing evidence indicates that the pain and physical disabilities resulting from arthritis are significant predictors

of depression. Differences in the experience of depressive symptoms are contingent on the severity of the medical condition, the body system (e.g., musculoskeletal) involved, and the patient's ability to maintain a positive body image, while acknowledging the loss of parts and/or of function. Factors such as location of the arthritis condition (e.g., knees, hands), total number of affected joints, type of arthritis condition (e.g., rheumatoid arthritis, osteoarthritis), and extent and type of physical limitations all have an influence on level of physical capacity which, in turn, affects the incidence and prevalence of depressive symptoms.

Systematic exploration of the psychosocial factors associated with arthritis conditions will help to identify the social, psychological, physical, and cultural factors that influence the patient's experience of the disease, as well as to understand the coping strategies that individuals use to combat its deleterious physical, psychological, and social outcomes.

## ASIAN AMERICAN/PACIFIC ISLANDER HEALTH AND BEHAVIOR

---

Asian Americans and Pacific Islanders (AAPIs) comprise the fastest growing group in the United States, yet knowledge about the status of this population

**Table 1** Growth Rate and Size of the Largest Asian American and Pacific Islander (AAPI) Groups, 1990-2000

Chinese	+48%	2.5 million
Filipino	+36%	1.9 million
Asian Indian	+106%	1.7 million
Vietnamese	+83%	1.1 million
Korean	+35%	1.1 million
Japanese	-6%	796,700
Other	+65%	
Total AAPIs in 2000		10,412,610

SOURCE: U.S. census 1990 and 2000.

is severely hampered by several factors: the invisibility of the population, the lack of data on the population as a whole as well as its constituent subgroups, the extreme diversity within the category AAPI, and assumptions about the health of this population, since little data exist to the contrary. The AAPI umbrella term encompasses persons whose familial origins are in the Far East, Southeast Asia, the Indian subcontinent, and the Pacific Islands. Prior to 1965, AAPIs comprised less than 1% of the U.S. population. The 1965 removal of national quotas in the immigration law has resulted in triple-digit growth each decade until 1990. The past decade saw a 50% increase in the total population, and AAPIs now make up almost 4% of the U.S. population, more than 10 million people (see Table 1). Demographic predictions show that by 2020, 6% or 20 million Americans will be of AAPI heritage. Over 75% of AAPIs live in seven states (California, Hawaii, New York, New Jersey, Texas, Illinois, and Washington), and by 2020, will be dispersed throughout the country.

Perhaps the most important note regarding this group is that the term *Asian American and Pacific Islander* is an ethnic gloss that aggregates more than 50 highly diverse national groups with very different beliefs, cultures, and, importantly, epidemiological patterns of health outcomes. Generalizations about this group as a whole are not valid. The health status of members of this population reflects wide between- and within-group differences and identifies the groups at highest risk for morbidity and mortality from various diseases. Researchers, however, are limited by the critical lack of valid, disaggregated, population-based data on the various AAPI population groups for most diseases.

## EPIDEMIOLOGY

First-generation immigrants comprise 70% of the AAPI population, and, as new immigrants, they are a significantly young population, while groups who have been here for almost 200 years have sixth- and seventh-generation members. Available statistics indicate low rates of most infectious and chronic diseases; however, these aggregated data are erroneous and misleading. Some groups have unusually high rates of some infectious diseases, and overall, AAPIs face rapidly rising rates of chronic illnesses. The top five diseases among AAPIs as a group and for men and women are listed in Table 2.

## CULTURAL INFLUENCES ON AAPI HEALTH STATUS

About 85% to 90% of diseases are related to lifestyle choices such as diet, exercise, smoking, birth rates and age at first birth, changing sexual practices, environmental risks, and other lifestyle changes that come with acculturation, such as use of screening and early-detection practices. Studies of AAPI groups who have migrated to the United States indicate that such lifestyle factors appear to account for a major portion of disease incidence and mortality rates. As AAPIs Westernize their lifestyles, their disease profiles begin to mirror those of the dominant U.S. society, and the change is apparent within one generation (President's Advisory Commission on Asian Americans and Pacific Islanders, 2001; Zane, Takeuchi, & Young, 1994). Some diseases, such as breast cancer and diabetes, are occurring at an even higher rate than for non-Hispanic White Americans. The patterns of change, however, are not uniform across groups and vary due to differences in traditional cultural practices, immigration histories, levels of acculturation to dominant American lifestyles, and socioeconomic constraints.

Thus, as noted, generalizations about this group are extremely problematic. Because the variables listed above affect the incidence, prevalence, morbidity, and mortality from diseases, inclusion of these behavioral variables in reporting the health status of any of the AAPI groups would significantly increase the validity of the findings. Each disease report will differ depending on the specific cultural group of focus, its social/historical context, and the gender, age, socioeconomic status, acculturation level, English proficiency, and degree of cultural integrity of the individuals as well as the group members.

**Table 2** Top Five Diseases Among Asian Americans and Pacific Islanders (AAPIs)

<i>All AAPIs, All Ages</i>	<i>Men 45 Years+</i>	<i>Women 25 Years+</i>
1. Cardiovascular diseases	1. Cardiovascular diseases	1. Breast cancer/other cancers
2. Cancers	2. Cancers	2. Cardiovascular diseases
3. Cerebrovascular diseases	3. Cerebrovascular diseases	3. Cerebrovascular diseases
4. Accidents	4. Diabetes Type 2	4. Diabetes Type 2
5. Diabetes Type 2	5. Accidents/chronic lower respiratory	5. Accidents/chronic lower respiratory

SOURCE: *National Vital Statistics Report*, 49(11), October 12, 2001.

Despite the inter- and intragroup variability, some similarities exist among the cultures within the AAPI category, such as religion, traditional healing systems, and health care decision-making processes, but individual variation is paramount.

The major religions of this population either have their roots in or are strongly influenced by Buddhism, Confucianism, Taoism, and Animism. These religions all have a strong inner locus of control and preventive health focus. The basic concept of these worldviews is harmony among the elements utilizing the concept of balance of opposite life forces. Health is a balance of these life forces physically, emotionally, interpersonally, and with nature. The major traditions in healing, such as Ayurveda (East Asian medical system based in Hindu philosophy) or traditional Chinese medicine, can be traced back over several millennia. Native Hawaiians have a system of *pono* or equilibrium as well. Within these systems, the mind, body, spirit, and universal forces function as an integrated system. Balance among these systems is health, and imbalance results in illness. This integrated worldview of mind, body, and spirit produces an awkward interface with Western biomedicine, which separates physical from mental health, and leaves spirituality on the periphery.

In general, traditional AAPI diets, exercise patterns, and social practices seem protective against heart disease, diabetes, and the major cancers in the United States. Traditional AAPI diets are usually high in complex carbohydrates, fruits, and vegetables, and low in saturated fats and total calories.

Traditional diets may also be problematic, however. Some groups consume diets very high in sodium such as soy and fish sauces, and pickled, smoked, and salted foods, which contain nitrates that increase the risk of stomach cancer (the highest rates in the world are in Asia) and peppered foods may also contribute to higher stomach cancer rates. Korean men have the

highest rates of stomach cancer in the United States. South Asians often cook with *ghee*, a type of butter, and fry many foods, and their rates of diabetes and cardiovascular disease are among the highest for AAPIs. According to the National Institute of Diabetes and Digestive and Kidney Diseases, over 90% of Asians and Pacific Islanders are lactose intolerant (see [www.digestive.niddk.nih.gov](http://www.digestive.niddk.nih.gov)), and calcium intake is lower than U.S. diets. Many elderly Asian American women have osteoporosis.

The Westernization of Asian American and Pacific Islander diets has been shown to negatively affect their overall health status. Animal meat and fat generally replace fish as the primary sources of protein. Simple carbohydrates, such as breads, sugared confectionaries, and fast foods, replace more complex carbohydrates, and intake of fresh fruits and vegetables drop dramatically. The rates of cardiovascular disease, diabetes (rates of 15-20% compared to 4% for the U.S. population), and cancers associated with obesity and reduced roughage, such as breast, colorectal, and prostate, are increasing dramatically. Yet certain cancers are reduced compared to their rates in Asia, but still remain higher than Whites, such as Vietnamese men with 11.3 times the rate of liver cancer, Vietnamese women with 8 times the rate of cervical cancer, and Korean men, who have the highest rates of stomach cancer of all ethnic groups. The incidence of tuberculosis is almost 15 times that of Whites for Chinese and Filipinos, and hepatitis B carrier rates are about 14% for AAPIs compared with < 0.2% for the U.S. all ethnicities.

Smoking rates in Asia for men are significantly higher than in the United States, and recent immigrants/refugees bring these practices with them. AAPI men have the highest smoking rates in the United States (ranging from 28% in Chinese Americans to 65% in Tongan and 72% in Laotian and Cambodian men). AAPI women, however, experience the opposite

pattern. Smoking rates are very low in their native Asian and Pacific Islander countries (~2-5%), but are rising rapidly in the United States, as they become more acculturated (5-12%). Young women (ages 16-25) have rates of 20% to 40% on informal surveys.

Physical activity seems to be extremely low in AAPIs. For example, in the 1999 Behavioral Risk Factor Surveillance System (BRFSS, a state-based system of health surveys) in Hawaii, the physical inactivity level for Caucasians in Hawaii was approximately 68%, whereas for all the AAPI groups, the range of inactivity was 70% for part-Hawaiians to 79% for Chinese.

Drinking behavior among particular AAPI groups is significantly different from the general U.S. population. On the whole, AAPIs who drink habitually drink more per day than any other racial/ethnic group, and between 1994 and 1999, AAPI substance abuse treatment admissions rose by 52%.

#### TRADITIONAL HEALTH PRACTICES AND HEALTH CARE DECISION MAKING

At least 20% to 70% of AAPIs use traditional healing practices preventively, sequentially, or concurrently with Western biomedicine. Many of the traditional practices are effective, such as massage, acupuncture, and herbs. When used concurrently with biomedical drugs, however, harmful interactions can occur.

Cultural beliefs and practices affect not only the biological risk factors for disease but also the existential and experiential meaning of particular diseases. How individuals weigh the costs and benefits of screening, early detection, treatment, and rehabilitation are culturally as well as individually determined. Therefore, incorporating an assessment of the meaning of the disease as well as risky behavior into the study of ethnic differences in incidence and mortality rates would provide more accurate information on the cultural meaning of the disease to the patient and family, which, in turn, would affect each stage of health care, such as decisions to seek care, their choice of treatments, and degree of adherence to treatment protocols. Thus, the source of within- and between-group differences may be more apparent if the effects of cultural beliefs, values, and practices along the continuum of care were identified. Cultural differences in communication etiquette between practitioners and patients and families also affects

their sense of trust and safety, and, subsequently, their health care decisions and actions (Kagawa-Singer & Chung, 2002).

Recognition of the unique needs of the heterogeneous groups within the AAPI population will enable researchers and clinicians to more accurately address the health needs of this cultural group.

## ASTHMA: BEHAVIORAL TREATMENT

---

Asthma is a chronic respiratory disease that is marked by intermittent and variable periods of breathing difficulty. Individuals with asthma demonstrate hypersensitivity to a range of triggers (e.g., allergens, pollutants, infections, stress) that results in swelling, obstruction, and mucus in the airways. Typical symptoms involve wheezing, shortness of breath, chest tightness, and coughing. In recent years, the prevalence, morbidity, and mortality associated with asthma have increased substantially. This rise has been particularly pronounced among ethnic minorities, inner-city communities, and low-income populations. Despite considerable medical advances that have improved the understanding of asthma and enhanced the ability to effectively treat this chronic condition, asthma remains a leading cause of health care utilization and costs.

One explanation for the persistent morbidity associated with asthma involves the behavioral challenges inherent in effectively managing the chronic condition. For instance, widespread nonadherence to asthma medications has been documented among adult and pediatric patients, with patients taking, on average, only about half of their regularly prescribed medications.

Effective asthma management typically requires a combined approach that integrates behavioral strategies (e.g., symptom monitoring) within the context of medical treatment. An integrated approach incorporates three basic behavioral recommendations. First, avoiding triggers is emphasized in order to prevent symptoms and limit the severity of asthma episodes. Avoiding triggers includes staying away from irritants (e.g., tobacco smoke, cold dry air) and allergens (e.g., animal dander, dust, mold). Second, given that medical treatment often involves use of multiple medications over time, treatment plans should be constructed to maximize patient adherence. Prescribing medications that are more convenient to use, require less frequent dosing, and have minimal side effects is more likely to facilitate adherence. Third, ongoing symptom monitoring through the use of a peak flow meter, symptom records, and regular feedback to a physician is critical to determine if adjustments in treatment approach are necessary. An additional component of symptom monitoring involves seeking appropriate health care services (e.g., physician "sick visit," emergency department visit) if indicated.

When children and adults continue to have difficulty with asthma despite an integrated approach, supplemental psychosocial interventions are often recommended. Specialized behavioral interventions have been applied to assist patients with poorly managed asthma, and include educational efforts, cognitive-behavioral therapy, and family therapy to supplement medical interventions.

Providing asthma education as a route to promoting appropriate management behaviors is the most common strategy. Results from studies examining the effectiveness of asthma education have been mixed. A meta-analysis of asthma education programs for children concluded that these programs had limited effects on morbidity (Bernard-Bonnin, Stachenko, Bonnin, Charette, & Rousseau, 1995). Helping patients to better understand their disease and the importance of effective asthma management appears to be a valuable stepping-stone, but educational

efforts in the absence of behavioral strategies typically do not result in sustainable improvements in morbidity and adherence. As a result, intervention efforts that combine education with behavioral techniques, such as cognitive-behavioral skills, stress management, and family therapy, are the most promising approaches.

Cognitive-behavioral interventions include a range of strategies aimed to maximize the frequency and effectiveness of self-management behaviors, such as medication adherence and trigger avoidance. Problem-solving therapy has been identified as a tool that can be used effectively by children, families, and adults to identify barriers to mismanagement (e.g., forgetting to take medications) and adopt strategies to circumvent barriers (e.g., using a daily calendar to monitor medication use). Cognitive-behavioral techniques can also be used to help patients recognize early signs of breathing difficulty and respond appropriately according to a predetermined action plan. As emotions have been shown to trigger asthma exacerbations for a portion of individuals, specific techniques to decrease anxiety and tension, such as relaxation training and biofeedback, have also been investigated. Generally, these programs have been found to be useful adjuncts in improving pulmonary function for individuals who have emotionally triggered asthma. Their efficacy to prevent asthma episodes, however, has not been demonstrated.

Family therapy has also been posed as an adjunct to asthma treatment, particularly in pediatric populations. The emphasis on family therapy is based on the theory that maladaptive patterns of family functioning influence asthma outcomes. Although intuitively appealing, family therapy approaches have not been tested rigorously, so it remains difficult to determine their efficacy.

Behavioral approaches to asthma management have become an integral part of the standard of care. The importance of combining behavioral aspects of care, such as asthma knowledge and self-management skills, with medical management has been documented in the literature and is evident in clinical practice. Behavioral intervention protocols may also be used as adjunctive treatment with particularly challenging cases. Identifying patients in need of adjunctive treatment beyond basic behavioral approaches, such as cognitive-behavioral treatment to promote adherence, is another role of behavioral medicine in the area of asthma. Promoting the integration of behavioral and medical management, identifying

patients in need of adjunctive treatment, and selecting the treatment that best fits the identified psychosocial issue will likely yield the best clinical outcomes.

## ASTHMA AND STRESS

---

Although consensus has emerged from the clinical, social science, psychological, and biological literature that psychosocial factors affect asthma morbidity, their role in the asthma remains controversial since mechanisms are not well understood. This entry highlights significant insights into this field from a multidisciplinary perspective rather than being an exhaustive overview of the subject. Behavioral, neural, and immunologic pathways are examined, underscoring reciprocal relations that might link psychological factors to both the onset of asthma and exacerbation of established disease.

### HISTORICAL PERSPECTIVE

Early references to the importance of emotional and psychological processes were put forth in a treatise

on asthma by Maimonides, an influential medieval rabbi, philosopher, and physician. Sir William Osler referred to asthma as “a neurotic affection” in his medical textbook, which served as a cornerstone of medical teaching in the latter part of the 19th century. Indeed, before we understood the inflammatory basis of asthma, it was among the disorders believed to be “purely” psychogenic in origin and was commonly referred to as *asthma nervosa*.

Early research in this area was strongly dominated by psychoanalytic theory, an extension of the Freudian idea that symptoms were a symbolic expression of unconscious conflicts and repressed desires. The so-called specific emotion theory was developed in large part by Alexander and colleagues at the Chicago Institute of Psychoanalysis beginning in the 1930s. Concurrently, learning theorists argued that particular emotional experiences may have reinforced pulmonary physiologic responses, thus increasing the likelihood of their recurring in the same context. Eventually, purely psychoanalytic and behavioral formulations gave way to physiological studies providing more objective support for the idea that emotions play an important role in asthma. Stress and psychological factors have been associated with asthma symptomatology and with bronchoconstriction and reduction in pulmonary flow rates.

To explore potential mechanisms linking stress and asthma, it is helpful first to consider how stressors may influence disease in general and second to frame these hypotheses within the current asthma paradigm.

### LIFE STRESS MODEL

When faced with environmental demands, individuals appraise whether the event is threatening or potentially overwhelming to their existing coping resources. If environmental demands are found to be taxing or threatening, and coping resources are viewed to be inadequate, we perceive ourselves as being under stress. This perception is presumed to result in negative emotional states including fear, anger, anxiety, and depression. Changes in behavioral and emotional states that accompany the perception of, and adaptation to, environmental circumstances are accompanied by complex patterns of neuroendocrine and immunologic changes.

### CURRENT ASTHMA PARADIGM

Asthma and allergic disease are understood to be chronic inflammatory processes regulated through

immune phenomena in which many cells (i.e., mast cells, eosinophils, and T lymphocytes) and associated cytokines play a role. Evidence supports the role of complex neural mechanisms and alterations of autonomic nervous system control in the pathophysiology and symptomatology of asthma. Hormones and neuropeptides released into the circulation when individuals experience stress are also thought to be involved in regulating both inflammatory and airway responses. Furthermore, self-management of disease is a cornerstone of current asthma guidelines. Poor self-management has been linked to poor asthma outcomes. Factors important to adherence include asthma knowledge, skills, and management behavior. In addition, these variables are known to be affected by mental health, social support, and personal health beliefs and behaviors.

To simplify the discussion, the relations between stress, psychological dysfunction, endocrine/neural/immune function, social connectedness, and behavior will be reviewed separately in order to explore the influence of stress on asthma. It should be understood that this is a rudimentary approach, as contemporary attempts to apply the biopsychosocial model to disease emphasize that a unidirectional model is too simplistic; causality is at least bidirectional or reciprocal and more probably cyclic in complexity.

## PSYCHOLOGICAL STRESS AND THE ENDOCRINE SYSTEM

Psychological stressors have been associated with the activation of the sympathetic and adrenomedullary system and the hypothalamic-pituitary-adrenocortical (HPA) axis. These systems respond to psychological stress with increased output of adrenaline (epinephrine) and noradrenaline (norepinephrine) from the adrenal medulla. The hypothalamus produces corticotropin-releasing hormone (CRH), which triggers the anterior pituitary gland to secrete adrenocorticotrophic hormone (ACTH), which, in turn, activates the adrenal cortex to secrete corticosteroids. Recent work suggests that negative emotional responses disturb the regulation of the HPA system. Shifts in the circadian rhythm of cortisol have also been found among persons in stressful situations. Other regulatory pituitary (i.e., corticotropin) and hypothalamic hormones (i.e., CRH and arginine vasopressin) of the HPA axis have systemic immunopotentiating and proinflammatory effects. Alterations in a range of

other hormones, neurotransmitters, and neuropeptides (growth hormone, prolactin, natural opiate beta-endorphins and enkephalins) found in response to stress may also play a part in the health effects of stress. Histamine, which is produced by mast cells, may suppress cellular immune function and potentiate a Th2 shift in humoral immune function.

## PSYCHOLOGICAL DISTRESS AND ASTHMA

Asthmatic subjects frequently have associated underlying psychological distress (depression and anxiety). Development of psychological distress in children has been associated with asthma that is more difficult to manage, requiring higher doses of steroids, more frequent and prolonged hospitalizations, and greater functional disability. Asthmatics with comorbid psychological symptoms are more often noncompliant. Psychological morbidity has been linked to asthmatic mortality. Asthmatic subjects have been characterized by beta-adrenergic hyporesponsiveness and alpha-adrenergic and cholinergic hyperresponsiveness. Defects in the function of the autonomic nervous system have also been demonstrated in psychological states. In depression and posttraumatic stress disorder, studies of central mediators in the brain also demonstrate parasympathetic hyperresponsiveness and beta-adrenergic hyporesponsiveness. Increased alpha-adrenergic and cholinergic responsiveness distal from the airway has also been demonstrated in asthmatic patients, raising the question of common biological pathways.

## STRESS AND AUTONOMIC CONTROL OF AIRWAYS

The argument that psychological stress influences autonomic control of the airways is based primarily on the fact that many of the same autonomic mechanisms thought to play a role in asthma are involved in the activation and regulation of physiological responses to stress. These mechanisms include the release of sympathetic nervous system mediators and the action of adrenergic (sympathetic) and cholinergic (parasympathetic) nerves and the neurotransmitters and neuropeptides they produce. Recent experimental studies in which asthmatic patients are exposed to stressful situations have focused on stress-induced vagal reactivity as a mediator of emotionally induced bronchoconstriction. Although human airway smooth

muscle is not functionally innervated by adrenergic axons, studies have shown adrenergic innervation of submucosal glands, bronchial blood vessels, and airway ganglia. The regulatory effects of adrenaline and noradrenaline on adrenoceptors suggest a plausible mechanism by which stress-induced activation of the sympathetic nervous system might influence bronchomotor tone.

It seems paradoxical that activation of the sympathetic nervous system by stress, resulting in release of mediators with a beta agonist effect, should relax airway smooth muscle, and that acute psychological stress, which is accompanied by a rapid increase in circulating catecholamines, should consequently cause bronchodilation. However, the stress-induced response of the autonomic nervous system is more complex and variable. The relative strength of sympathetic versus parasympathetic control in response to certain forms of stress differs with the individual, with some showing a predominantly parasympathetic response. Such individuals may be particularly susceptible to stress-induced bronchoconstriction.

## STRESS AND IMMUNE FUNCTION

A substantial literature exists that demonstrates that psychological stress can influence cell trafficking, cell function including mitogen-stimulated blastogenesis and natural killer cell cytotoxicity, and lymphocyte production of cytokines. Stress can modulate immune response through nerve pathways connecting the autonomic nervous and immune systems, by triggering the release of hormones and neuropeptides that interact with immune cells, and through the impact on behaviors such as smoking and drinking alcohol that are adopted as ways of coping with stress.

Stress is not expected to have the same effects on immune function in all people. As noted earlier, individual differences in response to stressful events are attributable to interpretation of the event, access to coping resources, and presence of antecedent chronic stress. However, there is also evidence of stable individual differences in immune response that occur independent of psychological response to the stressor. When exposed to multiple acute laboratory stressors over time, some subjects consistently demonstrate stress-elicited alterations in immunity, while others do not. Factors (like stress) that stimulate the immune system at critical periods during development may be important in inducing functional changes in neural,

immune, and endocrine components that affect one's perception of and response to subsequent stimuli. For most children who become allergic or asthmatic, the polarization of their immune system into an atopic phenotype probably occurs during early childhood. It has been speculated that stress triggers hormones in the early months of life, which may influence Th-2 cell predominance, perhaps through a direct influence of stress hormones on the production of cytokines that are thought to modulate the direction of differentiation.

## STRESS AND INFECTION

Psychological stress may influence the pathophysiology of asthma by increasing the risk of respiratory infections. The role of respiratory tract infection in asthma is fairly well characterized with current evidence indicating that viral, as opposed to bacterial, infections are the most important infectious agents. A number of mechanisms may be involved. First, viral respiratory infections damage the airway epithelium, causing inflammation. Another mechanism involves the stimulation of virus-specific IgE antibody. Respiratory syncytial and parainfluenza viruses may potentiate the allergic response to allergens by increasing the release of inflammatory mediators from mast cells and the subsequent cascade of inflammatory events characteristic of asthma. Last, viral respiratory infections may also result in the appearance of a late asthmatic response to inhaled antigen. Thus, there is evidence that viral infections are an "adjuvant" to the inflammatory response and promote the development of airway injury by enhancing airway inflammation.

A potential consequence of stress-induced changes in immune response is suppression of host resistance to infectious agents, particularly agents that cause upper respiratory disease. The primary evidence for such effects comes from studies of psychological stress as a risk factor for respiratory infections. Increased incidence of upper respiratory infections under stress in these epidemiological studies may be attributable either to stress-induced increases in exposure to infectious agents or to stress-induced changes in host resistance. Control for exposure is provided by studies in which volunteers are intentionally exposed to a virus—that is, viral-challenge trials. Using this paradigm, psychological stress has been associated with the incidence of infection and illness, with increasing stress related in a dose response manner to increasing risk of infection.

## PSYCHOLOGICAL STRESS AND OXIDATIVE STRESS

A recent hypothesis put forth by Spiteri and colleagues postulates that the inability to detoxify reactive oxygen species (ROS) among atopic subjects then leads to prolonged inflammation, the release of chemotactic factors, the activation and recruitment of immune effector cells, and the stimulation of bronchoconstricting mechanisms. Bronchoconstriction can be triggered by the upregulation of bronchoconstriction eicosanoids. Clinically, atopic subjects either unable to detoxify ROS or overwhelmed by a chronic elevated burden of ROS may develop the onset or aggravation of respiratory symptoms. In way of extending Spiteri and colleagues' hypothesis, one may posit that factors that may predispose susceptible subjects to asthma are chronic exposure to oxidative toxins (tobacco smoke, air pollution) and other *environmental* factors that may augment oxidative toxicity and increase airway inflammation, including psychological stress.

## STRESS AND SOCIAL CONNECTEDNESS

Ecological views on health promotion underscore the significance of the social context within which individuals live and the importance of social relationships. Lack of social relationships has been linked to an array of adverse health outcomes and physiological effects including altered immunologic functioning. Social support may reduce or buffer the deleterious effects of stress by altering the perception of a situation or facilitating more appropriate coping. Greater social network diversity has been related to less anxiety, depression, and nonspecific psychological distress. Social supports may operate through influence on health-promoting behaviors such as abstaining from cigarette smoking, moderating alcohol consumption, improving diet, exercise, and sleep quality. Social support/networks may also buffer direct effects of stress on biological functioning and thus have an impact on asthma.

## ENVIRONMENTAL STRESS AND HEALTH BEHAVIORS

Because self-management is so critical in asthma care, it is important to consider how stress may affect self-management strategies and adherence to prescribed treatment plans. Social learning theory provides a

useful model that examines the interaction among individuals, environments, and health behaviors. Perceived control has been identified among factors that mediate the experience of chronic illness. Interactions between individuals and the environment are key to development of perceived control. Individuals repeatedly exposed to aversive events they cannot predict or control—for example, poverty, adverse life events, living in an unsafe or unpredictable environment—may learn to become helpless. Lack of perceived control may undermine symptom perception and disease management efforts.

## LIFE STRESS, SOCIOECONOMIC STATUS, AND RACE

In the United States, asthma morbidity disproportionately affects poor, urban minority populations. Efforts to identify factors related to these disparities are needed. The adverse association between poverty and ethnic minority status and asthma outcomes may in part be due to differential exposure to and perception of life stress as has been postulated for other health outcomes. Given the renewed interest in the influence of psychological stress on asthma, this is a useful way to conceptualize community-level influences on health whether one operationalizes the environment as a social or a physical construct. Both physical and social factors can be a source of environmental demands that contribute to stress experienced by populations living in a particular area. Various sociodemographic characteristics (e.g., lower social class, ethnic minority status, gender) may predispose individuals to particular pervasive forms of chronic life stress, which, in turn, may be significantly influenced by the characteristics of the communities in which they live. Future studies need to examine the links among these social influences (and the heightened stress that they may elicit) as risk factors for childhood asthma analogous to physical environmental exposures (e.g., allergens, tobacco smoke, air pollution). Such studies are likely to further our understanding of the increased asthma burden on populations of children living in poverty in urban areas or other disadvantaged communities.

## SUMMARY

Stress is multifactorial exposure and may have properties beyond oxidation that can ultimately lead

to asthma. Environmental stressors may affect asthma through neuroimmunologic mechanisms that are adversely impacted and/or buffered by social networks, social support, and psychological functioning. In addition, life stress may affect health beliefs and behaviors that may affect asthma management. Whereas earlier psychosomatic models have supported a role for psychological stress in contributing to variable asthma morbidity among those with existing disease, a growing appreciation of the interactions between behavioral, neural, endocrine, and immune processes suggests a role for these psychosocial factors in the genesis of asthma as well.

While a causal link between stress and asthma has not been established, this entry provides a framework in which we can begin to see links between these systems that might provide new insights to guide future explorations. The complexity of these interactions underscores the need for a multidisciplinary approach that combines the idea that the origin of asthma is purely psychogenic in nature with the antithetical consideration that the biological aspects are all important. These distinctions are artificial, and future research that synthesizes biological, psychological, sociocultural, and family parameters is urgently needed to further our understanding of the rising burden of asthma.

## AUTOIMMUNE DISEASES: PSYCHOSOCIAL ASPECTS

---

Autoimmune diseases result when the immune system becomes dysregulated and directs its attack not toward foreign invaders, but toward one or more aspects of the body's own healthy organ systems. The consequences of this dysregulation range from relatively mild manifestations, such as hay fever, to life-threatening illnesses. More than 80 serious chronic autoimmune illnesses have been identified, including diseases that involve the skin and connective tissues (e.g., rheumatoid arthritis [RA]), and the endocrine (Grave's disease), nervous (e.g., multiple sclerosis), and gastrointestinal (e.g., inflammatory bowel disease) systems. The underlying causes of autoimmune diseases are still under investigation, but several prevalence patterns provide clues about factors that may contribute to their development. Because autoimmune diseases cluster in families, for example, these illnesses are thought to have a genetic component. In addition, autoimmune diseases are about 3 times as likely to occur among women compared to men, and are particularly prevalent during childbearing years, suggesting that reproductive hormones may play a role. It is important to keep in mind as well that different biological mechanisms underlie each autoimmune condition.

Although immune system activity is a key factor in progression of autoimmune disease, adaptation involves a complex interplay of biological, psychological, and social factors. Not only do the symptoms and physiological underpinnings of autoimmune disease have consequences for psychological and social functioning, but also psychological and social factors influence immune activation and suppression, to affect how individuals respond to their disease in mind and body.

Among the most widely studied psychosocial factors is social stress, which has been associated with dysregulation of immune factors known to influence the course of autoimmune disease. Although stressful events were initially studied for their role in suppression of immune function, more recent studies have found evidence that stress may also activate aspects of the immune system, especially proinflammatory processes. For example, Zautra, Smith, and Yocum (2002) have found greater T-cell activation as well as increased pain among RA patients following a stressful week, with proinflammatory cytokines such as interleukin-6 implicated. Mohr et al. (2000) found evidence of new brain lesions in multiple sclerosis patients following conflict and disruption in routine. Stress-related changes in the hypothalamic-pituitary-adrenal (HPA) system have well-established effects on immune functioning. Elevations in cortisol, for example, suppress immune function, and Sternberg and colleagues have offered the hypothesis that some autoimmune conditions such as RA are a consequence of an insufficient cortisol response. Other stress-related hormones are likely to be involved as well. Moderate increases in prolactin promote immune activation. This pituitary hormone is often elevated during stress and has been found higher in RA than osteoarthritis patients with comparable pain. Although the focus of most studies has typically been on the HPA system, there is also evidence of sympathetic nervous system involvement.

Chronically stressful situations may also reduce the sensitivity of the receptors on immune cells to the anti-inflammatory actions of hormones like cortisol. Coping responses that fail to resolve the stressful situation may lead to chronic distress with accompanying feelings of helplessness and depression. Persons with clinical depression have elevations in proinflammatory cytokines such as IL-6, which are also elevated in some autoimmune conditions such as RA, suggesting that affective disturbance is a key cofactor in disease course (Maes, Song, Lin, et al., 1998). These influences may be reversible through interventions that elevate positive affect and provide means to better regulate negative emotions. Early evidence of such relationships has been found in studies that manipulated positive emotion and found a reduction in levels of proinflammatory cytokines. It is important to keep in mind, however, that models of unidirectional cause and effect relationships often must give way to bidirectional relationships to fully capture the processes

that underlie relationships between immune function and human emotion.

Social networks may be a source of strength as well as a source of stress. There is empirical evidence that patients with an autoimmune disease with good versus poor support systems show less active disease and functional impairment over time. Other researchers have also offered evidence that social ties are health promoting, and there are many pathways through which these associations may be traced: greater motivation to engage in healthy behaviors, quicker recovery from psychological distress following stressful events, and more resilient physiological responses following an adaptation challenge.

One outgrowth of the acknowledgment that psychological, social, and physiological processes contribute to autoimmune conditions is the development of psychosocial interventions. Among the most common forms of treatment is cognitive-behavioral therapy (CBT), which typically targets improvement of aspects of health status, such as pain tolerance, mobility, self-management, and self-efficacy. CBT may include training in progressive relaxation, rational thinking, active coping skills, goal setting, and stress management. It is not intended to replace more biomedically oriented approaches, but rather to complement the standard biological treatments offered to patients. Evidence to date suggests that CBT is an efficacious treatment, resulting in decreased pain, depression, disease activity, and health care utilization among patients with autoimmune disorders.

More recently, studies have yielded findings that suggest that increasing the opportunity for emotional expression may have beneficial effects for those with autoimmune disorders. In one study, RA patients were randomly assigned either to talk privately about a stressful event or to discuss a trivial topic for 15 minutes on 4 consecutive days. Patients who discussed a stressor had less physical dysfunction and less affective disturbance at the 3-month follow-up than did those who discussed a trivial event. There were no differences in pain or joint condition, however. Another investigation used a similar paradigm and found that at 4-month follow-up, RA patients who wrote about traumatic events showed improved health status and less disease activity than did those who wrote about their daily plans. These findings suggest that a focus on emotional disclosure may yield significant benefits, at least among RA patients, and highlight the potential of emotional processes as an important

target in psychological interventions for patients with autoimmune disease.

Interventions that center on reinforcing social support among patients with autoimmune disease have yielded less promising results. For example, supportive-expressive group therapy (SEG) did not improve levels of distress and other symptoms in systemic lupus erythematosus patients over and above the effects of usual care at 12 month follow-up. Among multiple sclerosis patients with major depressive disorder, patients treated with either CBT or antidepressants showed greater reductions in depressive symptoms compared to those treated with an SEG intervention at 12-month follow-up. In another study, the addition of a family support component did not enhance the efficacy of a CBT intervention designed to control RA symptoms. Both CBT alone and CBT with support interventions showed significant improvement in joint pain and swelling relative to a no-treatment control. Whether supportive interventions alleviate symptoms and enhance functioning among autoimmune patients remains an open question.

Although CBT and other psychosocial treatments have generally produced significant clinical benefits, the mechanisms by which these benefits accrue have remained largely unexplored. In particular, relatively little is known about the impact of psychosocial interventions on immune function or stress-responsive hormones. One exception is the work of Mohr and colleagues (Mohr, Goodkin, Islar, Hauser, & Genain, 2001), who examined the relationship between levels of a proinflammatory cytokine, interferon (INF)-gamma, and depression symptoms among depressed multiple sclerosis patients. Depressive symptoms were positively related to INF-gamma production prior to treatment, and both INF-gamma and depressive symptoms decreased in response to treatment. This study needs to be replicated and the findings tested to see if they would apply to other autoimmune conditions. Nevertheless, they suggest that treatment of depression may affect levels of proinflammatory components of the immune system, and may therefore provide both symptom alleviation as well as a novel disease-modifying therapeutic strategy for patients with multiple sclerosis, and perhaps those with other autoimmune disorders.

Autoimmune diseases offer a window into mind-body relations that is inviting to both basic scientists and also clinical health researchers. In these conditions, the psychosocial variables affect biological as well as behavioral substrates that underlie the signs

and symptoms of disease. The interdisciplinary issues are daunting, to be sure, but the promise is great for those biobehavioral researchers with a high tolerance for ambiguity and who can openly engage with scientists outside their own disciplines.

## BEHAVIORAL GENETICS AND HEALTH

---

Behavioral genetics (also known as quantitative genetics) involves the examination of a wide range of factors for scientific investigation. The “behavior” in behavioral genetics is not limited to those studied by social scientists. From social behaviors such as attachment to psychological variables such as intelligence to health variables such as blood pressure, behavioral genetics approaches have been applied.

Behavioral genetics originally became a field of inquiry, in part, in opposition to the developmental “environmentalist” view that only factors from the environment are involved in interindividual variability in the development of children. Just as erroneous a view is that genes are the most important factors involved in interindividual differences. Recent advances in molecular genetics techniques have significantly increased our ability to understand the contribution of genes to health and illness. However, the inclination to believe that genes account for all or none of the differences between people is “genetic determinism” and does not accurately represent the assumptions of behavioral genetics methodologies. For example, some suggest that disease processes arise from early environment. If the prenatal environment does affect diseases such as Type 2 diabetes or hypertension and identical twins are highly concordant for these conditions, genetic explanations are not the only viable interpretations. It may be due to adverse environments in the womb.

One of the potential dangers in emphasizing the presence of genetic influences and ignoring environmental factors is that society and policymakers will invest less in changing environments. One must keep in mind that behavioral genetics methods operate under assumptions of the collective contribution of genes *and* environment, *not* nature *versus* nurture. So the interventions to improve health will be most effective when combinations of environmental manipulations and gene therapies (when appropriate) are developed. This entry presents a brief introduction to behavioral genetics methodology and then a brief review of some research from the past 15 years using this approach.

### GENERAL BEHAVIORAL GENETICS METHODS

Traditionally, behavioral scientists and epidemiologists have tended to attribute behavioral variation only to environmental sources. During the past decade, however, most researchers have come to accept the notion that genetic factors are, in part, responsible for individual variation on many measures of behaviors. Using a behavioral genetics approach, origins of individual differences are conceptualized to derive from additive genetic and environmental sources of variance and thus, in theory, account for the total behavioral or phenotypic variation (phenotypic variation refers to the pattern of scores that results from studying the behavior of interest).

Additive genetic variation is the sum of the effects from genes influencing a trait. In some disease processes such as phenylketonuria or Huntington’s

chorea, single genes have been found to be responsible in the formation of the disease states. These examples of one-gene, one-disease (OGOD) scenarios are typically not the case for most behavioral phenomena nor are they the premise of quantitative genetic analyses. The underlying premise is that multiple genes or pleiotropy is involved in genetic effects that are observed in a trait.

Although the name *behavioral genetics* (sometimes used in place of quantitative genetics) implies an emphasis on heritable aspects of behavior, the identification of environmental influences on a phenotype is equally important in this type of analysis. Environmental effects are partitioned into those that are common (shared) or unique (nonshared). Common/shared environmental variation is the phenotypic variation due to the subjects living in the same family, thus sharing the same environment.

Unique/nonshared environmental variation is the component of phenotypic variance that can be attributed to the environmental factors not shared by family members and thus making members of the same family different from one another. One hypothesis posed about the outcome of such studies on older populations is that as individuals age, unique environmental factors will have a greater impact on the etiology of behavioral traits. This idea is derived from the speculation that as a person ages, he or she has a greater number of experiences that help to shape the behavioral trait of interest. It is, of course, hazardous to operate on speculation and conjecture rather than scientific data, and there is evidence that this scenario is not the case with several phenotypes in older individuals, such as cognitive abilities.

Behavioral genetics designs frequently take the form of twin studies. The classic twin study involves comparisons between identical or monozygotic (MZ) and same-sex fraternal or dizygotic (DZ) twin pairs (twin pairs that are genetically as alike as siblings but are born at the same time). There are several variations of this design but the classic twin study tends to be the most frequently used design. An assumption of behavioral genetics is that MZ twin pairs share 100% of their genes (DZ twin pairs share on average 50%). Using data from twin pairs and operating under this assumption, the heritability of a trait can be analyzed using several techniques. Heritability is considered the proportion of phenotypic variance that is due to genetic variation. A popular simple method for calculating heritability is to calculate twice the difference between

the intraclass correlations (the statistical calculation of how similar one twin is to the other) of MZ and DZ twin pairs. Shared environmental variance can be calculated by doubling the intraclass correlation for the DZ twin pairs and subtracting the MZ intraclass correlation. By subtracting the sum of the heritability and shared environmental estimates from 1.00, an estimate of nonshared environmental variance is obtained.

As in other social sciences fields, structural equation modeling (SEM) or biometrical modeling, the fitting of observed data to models of genetic and environmental effects, is the preferred method of behavioral geneticists to analyze data. These SEM techniques provide estimates that represent the relative contribution of genetic and environmental influences. Variances and covariances are used in the calculation of the components of variance (genetic, shared environmental, and unique environmental). The benefit of these techniques over the intraclass correlation method described earlier is that multivariate extensions can be performed to simultaneously assess shared and unique genetic and environmental relationships among two or more variables.

An example of a path diagram of a classic univariate twin model is shown in Figure 1. Path diagrams are useful in that they provide a visual display of correlational and causal relationships between variables. By employing path analysis, specific hypotheses about relationships between the variables are quantified by parameter estimates or path coefficients. In the model shown in Figure 1, the overall phenotypic variance is explained using three components: G-additive genetic variation, C-common or shared family environmental variation, and E-unique environmental variation. In Figure 1, G, C, and E are latent (unmeasured or unobserved) variables, and  $h$ ,  $c$ , and  $e$  are parameter estimates. In this figure,  $P_1$  represents the observed score for Twin 1 and  $P_2$  represents the score for Twin 2. It should be noted that the example provided here is the general example and that P could represent any phenotype, trait, or variable.

In model fitting, observed data are compared to expected values and the result is a familiar  $\chi^2$  statistic. Using these techniques, parameters are dropped from the model to see if a more parsimonious model (one with fewer parameters or latent variables, yet still fitting the data) is available to explain the data. Statistical significance of these parameters is assessed from maximum likelihood ratio  $\chi^2$  comparisons of the models after the parameters have been dropped.

**Figure 1** Structural Equation Model of Genetic and Environmental Influences

NOTE: G represents the additive genetic influences, C represents the shared environmental influences, and E represents the non-shared environmental influences. The h, c, and e represent the parameter estimates for each of the constructs.

Significance of parameters is evaluated by taking the difference between the  $\chi^2$ s of the full and reduced model and using that difference as a  $\chi^2$ . The degrees of freedom are calculated by taking the difference between the degrees of freedom for the full and reduced models. If there is a significant difference between two models, the parameter that was dropped is significant.

Using this basic model, then, if MZ twins are more alike than DZ twins, phenotypic variance can be attributed, in part, to genetic sources. If the genetic variation estimated by the parameter h represents a significant source of variation, this parameter cannot be dropped from the model without causing a significant change in  $\chi^2$  between the models. Squaring that parameter, h, provides an estimate of heritability. The contribution of shared and unique environmental factors to the phenotypic variation is also tested in this manner. For ease of comprehension, parameter estimates are typically standardized.

## BEHAVIORAL GENETICS STUDIES OF HEALTH

Perhaps now more than ever, health researchers acknowledge that behavior is a central underpinning of many chronic illnesses and diseases. There is great utility, then, in understanding the contribution of genetic and environmental influences in understanding behaviors associated with health. This information

may have the capacity to be the framework for public health guidelines developed to lower the incidence of chronic health conditions. Behavioral genetics methodology has been used to study many aspects of health for disease processes such as cardiovascular disease, cancer, and diabetes and risk factors for these diseases such as obesity, hypertension, and smoking. There is also growing interest in psychosocial measures associated with health such as stress. Below is an overview of the findings from numerous studies.

### Cardiovascular Disease

Heart disease continues to be the leading cause of death in the United States. Classic twin studies document significant genetic influences on cardiovascular stress patterns, and longitudinal studies suggest that heightened reactivity to stress constitutes a risk factor for the development of sustained hypertension.

Previous research on twins suggests that hereditary factors may be important determinants of cardiac dimensions and/or the degree of cardiac adaptability to physical conditioning. For example, small, dense LDL (LDL subclass phenotype B, these are the “bad” form of cholesterol) is a common, genetically influenced risk factor for coronary heart disease (CHD). Twin studies have also shown in higher concordance (twins both have the same phenotype or match) rates for premature CHD in MZ than in DZ twin pairs.

### Cancer

Twin studies of cancer show varying heritability estimates depending on type of cancer under investigation. Estimates of the genetic component for colon/colorectal cancer range from 10% to 35%, 27% to 43% for breast cancer, and 30% to 50% of the plasma fibrinogen. Estimates for lung cancer and melanoma are 14% and 18%, respectively. If assortative mating (people marrying based on a factor that is important to what is being studied, e.g., education) were important for liability to cancer, these heritability estimates may be an underestimation of the true genetic effects. Shared environments were equally important in colorectal cancer and melanoma, whereas no shared environmental effect has been found for lung cancer. The nonshared environmental effect for colorectal cancer, melanoma, and lung cancer is between 67% and 71%. The heritability estimates are much higher than those obtained from

family studies in which parents and offspring, or siblings, are compared.

### Diabetes

There are well-accepted links between genes and diabetes. Support for the notion of genetic influence in the development of NIDDM (non-insulin-dependent diabetes mellitus) has come from twin studies. Much of the recent research has focused on low birth weights of identical diabetic twins and the environment the child experiences in the womb. The shared-placenta MZ twins may experience a more adverse intrauterine environment compared to DZ twins and may therefore be more prone to develop various metabolic abnormalities. Some researchers have gone to the extent of creating models that include chorion type (the way twins are connected to their mother via the placenta) in their statistical modeling.

### Obesity

Obesity is thought to be at or near epidemic levels in this country and significantly contributes to cardiovascular diseases and diabetes. Children of obese parents have a substantially higher risk of adult obesity than children of lean parents, and adoption and twin studies have shown that this risk is largely genetic. Results from twin studies suggest that genetic factors explain 50% to 90% of the variance in body mass index or BMI (this is an index of the distribution of weight relative to a person's height). Studies that involved a combination of twins, adopted offspring, and other family relatives have also demonstrated relatively high heritability (40-70%) of many of the traits involved in obesity. These results are not only evident cross-sectionally but also longitudinally. Classic twin methods have estimated consistently high heritabilities for height, weight, and BMI. One might assume that there are genetic influences on food intake or perhaps even preferences for foods with low nutritional value. However, analysis of the heritability of intake has not shown food or taste preferences to have a strong genetic basis.

### Hypertension and Blood Pressure

Hypertension is associated with chronic and life-threatening illnesses such as CHD, kidney failure, blood vessel damage, and stroke. Estimates of heritability

range from 25% in pedigree studies to 65% in twin studies for sitting diastolic blood pressure.

In general, twin studies have suggested that about 30% of systolic blood pressure variance is attributable to genetic factors and 70% to environmental factors. While pertinent environmental factors such as salt intake, alcohol use, and amount of exercise also correlate significantly among relatives, only 7% of the total variance of diastolic blood pressure seems attributable to all shared environmental factors in family households.

### Smoking

The tremendous costs both at the individual and societal levels associated with tobacco use are well documented. Twin studies suggest that genetic factors influence smoking behavior. The data from family, adoption, and twin studies strongly support a substantial genetic influence on the initiation and maintenance of smoking. The literature supports the following hypothesis of the development of nicotine dependence. Smoking initiation is the obligatory first step. Research on the liability to initiating smoking show genetic influences of approximately 60%, shared and nonshared environmental influences of about 20% each. The impact of shared environment may be particularly pronounced in midadolescence when many begin smoking. A portion of those who initiate smoking go on to nicotine dependence. In this scenario, genetic factors appear to be more prominent, accounting for approximately 70% of the variance and shared environmental influences appear to be negligible. The genetic factors that predispose to smoking initiation appear to overlap substantially but not completely with those for nicotine dependence.

## GENETICS, ENVIRONMENT, AND HEALTH: INTEGRATION OF APPROACHES

The National Human Genome Research Institute (NHGRI) of the National Institutes of Health announced in June 2000 that it had developed a working draft of the human genome. This historic event places science on the doorstep of limitless possibilities including new insights about diseases and how to treat and prevent them. The trepidation about genetic approaches in the study of health by some scientists may arise from the inherent power in identifying biological mechanisms of disease and illness. Knowing

the sequence of the genome, however, is only the beginning. Equally important will be our knowledge of how the environment influences health, disease, and complex behaviors associated with health.

It is a correct assumption that investigations of health differentials across ethnic groups solely on the basis of genetic differences will not yield accurate identification of the mechanisms responsible for health disparities. Preconceived notions about genetically based racial inferiority have hindered advances in understanding and reducing health disparities. Attempting to explain the differential health burden ethnic minorities experience by genetic differences goes against probability given there are considerably small genetic differences across racial groups and more variability within each group.

The role of genetic influences, however, cannot be completely dismissed. The manner in which genes have the potential for playing a role in creating health differentials requires further explanation. It is not genes defining individuals from different ethnic groups that is key to the elucidation of health differentials per se. Instead, describing health differentials as arising from insults to a complex system represented by the interaction between genes and environments that creates excess burden of chronic illness and disease within some groups is a more accurate perspective.

In contrast to simply focusing on genetic explanations, there is ample information that differences in environmental factors between ethnic groups account for disparities in health status. Previous research on the significant impact of combinations of sociodemographic and psychosocial factors in disease processes and complex behaviors is perhaps our best indicator that science must avoid a reductionistic view. Genetic reductionism assumes that knowing and manipulating the genome will cure all our ills. Rather, we must understand how genetic and environmental influences work in concert to account for health conditions and the psychosocial variables that affect health. Much of previous research has focused on the behaviors and social structures that produce differences in health and disease across ethnic groups. One of the future and formidable challenges to using the information ascertained from adding genetic information to examinations of health differentials is to understand the underlying effect genes have on health and aging within complex environments or contexts. We may find that the polymorphisms (an alternate version of

a gene) that occur in genotypes (people's genetic architecture) are destructive or protective factors related to disease and health that are created, modified, or triggered by cultural and contextual factors.

Complementary, interdisciplinary approaches are desperately needed to harness the important findings that will come from the Human Genome Project and continued epidemiological research in the exploration of the underlying causes of health and illness and the related psychosocial behaviors. Continued use of behavioral genetics designs (and modified designs such as those mentioned here) will significantly advance our knowledge. Both conceptual and statistical advances in these methods are still required. These methods have the potential to provide the backdrop for exciting new revelations about how genes and environment work in concert to create health and illness.

## BEHAVIORAL RISK FACTOR SURVEILLANCE SYSTEM

---

The Behavioral Risk Factor Surveillance System (BRFSS) is a state-based system of health surveys. It was established in 1984 by the Centers for Disease Control and Prevention (CDC). Information on health risk behaviors, clinical preventive health practices, and health care access, primarily related to chronic disease and injury, is obtained from a representative sample of adults in each state. For most states, the BRFSS is the

only source for this type of information. Currently, data are collected monthly in all 50 states, the District of Columbia, and Puerto Rico; annual point-in-time surveys are conducted in the Virgin Islands and Guam. More than 200,000 adult interviews are completed each year, making the BRFSS the largest telephone health survey in the world. Not only is the BRFSS a unique source of risk behavior data for states, but the system is also useful to measure progress toward Healthy People 2010 objectives for the nation.

In behavioral surveillance, the BRFSS has a relatively long history. Beginning in 1984, 15 states initially participated. Data were collected on the six individual-level risk factors associated with the leading causes of premature mortality among adults: cigarette smoking, alcohol use, physical inactivity, diet, hypertension, and safety belt use. From its inception, the BRFSS was designed to allow states to add questions of their own choosing to their individual surveys. By 1993, the BRFSS had become a nationwide system and the total sample size exceeded 100,000. Beginning in 1988, optional, standardized sets of questions on specific topics (optional modules) were made available to states. The survey was redesigned in 1993, with certain questions asked every year (fixed core) and others asked every other year (rotating core). As part of the 1993 redesign, up to five “emerging” core questions for newly arising topics were included each year for all states.

Through the collection of behavioral data at the state level, the BRFSS has proven to be a powerful tool for building health promotion activities. As the demand for data has increased, there has been an increase in the number of requests to add questions to the survey. Currently, almost every division in National Center for Chronic Disease Prevention and Health Promotion and other CDC centers, institutes, and offices have questions on the BRFSS. Interest in the BRFSS has also grown outside of CDC. Other federal agencies, such as the Health Resources and Services Administration, the Administration on Aging, and the Veterans Administration, have added questions to the survey. There have also been requests for technical assistance from other countries that are eager to develop similar surveillance systems. The World Health Organization is developing a model surveillance system based on the BRFSS for export to any country.

For most states, the BRFSS is the only source of population-based health behavior data related to chronic disease. As the system has expanded, so have the

number of optional modules and state-added questions. In 2000, 19 optional modules were selected by states to add to their surveys. These are in addition to the approximately 80 core questions that are asked by all states.

With the growth of the system, some notable successes have been realized. Currently, all states use BRFSS data to establish and track state health objectives, plan health programs, or implement a broad array of disease prevention activities. Nearly two thirds of states use BRFSS data to support health-related legislative efforts. For example, in Delaware data were used to support legislation in publications, public hearings, and legislative sessions. A bill to create the Healthy Lifestyle and Tobacco-Related Disease Prevention Fund successfully passed. Two successful legislative initiatives were supported by data on the prevalence of smoking and mammography screening in Illinois—an act requiring no-smoking areas in public buildings and one requiring the inclusion of mammography screening in all health insurance coverage. In Nevada, BRFSS data documenting the state’s high rates of chronic and binge drinking were used to support legislation to place a per gallon tax at wholesale level on distilled alcohol. Only because the data were state specific could these efforts succeed.

As the usefulness of the BRFSS has increased, there has been a greater demand for more local-level data, that is, data at the district, county, or city level. Although the BRFSS was designed to produce state-level estimates, growth in the sample size has facilitated production of smaller area estimates. The need for prevalence estimates at the local level has led to the Selected Cities Project. Data from the 1997-2000 BRFSS are used to calculate estimates for selected urban areas in the United States with at least 300 respondents. This new use of BRFSS data has yielded estimates for nearly 200 metropolitan areas for the 1997-1999 combined data. The 2000 data provided estimates for 100 metropolitan areas. Preliminary results showed that the prevalence of certain behaviors varied across cities, not unlike the differences found across states. Variation in prevalence was also observed when cities were compared with their surrounding metropolitan areas and with the rest of the State. This new use of BRFSS data fills a critical public health need for local area surveillance data to support targeted program implementation and evaluation; and these data should help cities to better plan and direct their prevention efforts.

In addition to these achievements, there have been numerous analyses of BRFSS data and several published articles and reports, both by CDC and individual states. The majority of articles and reports have received wide dissemination in the literature and other media. State-specific reports have been used by several states for program planning and policy. Data from BRFSS were essential in identifying and tracking the epidemics of obesity and diabetes in the United States.

To facilitate use of BRFSS, data and reports are disseminated through the BRFSS Web site ([www.cdc.gov/brfss](http://www.cdc.gov/brfss)). The challenge for the BRFSS is how to effectively manage an increasingly complex surveillance system, which serves the needs of numerous programs, in the face of changing telecommunication technology, and the greater demand for more local-level data.

## BEREAVEMENT AND HEALTH

---

This entry examines the impact of bereavement throughout the life span as it relates to physical and mental health. A discussion of bereavement events will focus attention on the meaning of these losses through relevant theoretical perspectives and other bereavement-related factors such as gender, mortality, stress, health, and social support.

In general, bereavement is usually followed by a normal but painful adjustment to the loss. The bereavement process may become complicated as symptoms of depression frequently overlap with normal reactions to bereavement such as sleep disturbance, crying, weight loss, concentration difficulties, and anger or aggression. A factor associated with normal bereavement is the preexistence of life stressors that may coincide with the bereavement experience, such as low socioeconomic status, poor physical health, and the unavailability of a confidant. Physical health expressions may include a hollow feeling in the stomach, tightness in the chest and throat, dry mouth, sensitivity to noise, shortness of breath, muscular weakness, and lack of energy. Cognitive expressions may include disbelief, confusion, preoccupation with thoughts of the deceased, and an attempt to put the event into perspective and find meaning and understanding. Affective expressions are recognized as depression,

sorrow, sadness, guilt, anger, relief, and denial. Behavioral reactions may be the result of physical, affective, or cognitive changes and may present as a slowing down of movements or “longer reaction times” (Kalish, 1987, p. 35). In addition, there is the potential for the bereaved individual to develop health problems precipitated by an increase in self-destructive behavior, such as smoking, drinking, or overeating. Individuals may also experience an increased risk for an exacerbation of present health problems, which can lead to sudden death or suicide.

Role changes (following the death of a loved one) are said to represent a link between a major life event and stress. Stress is created directly by the individuals’ need to compensate or readjust to the disruption in their lives, and also indirectly through the increase in multiple roles. Stress can manifest itself in many forms in the human system: endocrine, immunologic, metabolic, cardiovascular, or particular diseases, and it has been associated with symptoms such as pain, depression, strain, fatigue, restlessness, panic, shortness of breath, headache, and tension (Parkes, 1972).

### BEREAVEMENT EVENTS

Depending on the type of loss, an individual may experience the loss as the status of a bereaved child; a bereaved spouse, sibling, or parent; or even a bereaved grandparent or great-grandparent.

#### Death of a Spouse

The strength of the bond with the deceased spouse tends to persist long after the initial year or two following the bereavement event. The death of a spouse may coincide with the physiological changes associated with aging and as a result lead to increased stress and a decline in physical or mental health. This may represent the loss of a sexual partner and companion; changes in decision making regarding household tasks, finances, and relocation; and changes in social roles and lifestyles. Widow(er)s live in a high-risk environment as a sense of hopelessness and helplessness may produce further stress and subsequent health problems or illness. In addition, the supportive nature of the relationship is lost in which reminders or cues are absent for important daily activities. Meaningful relationships from friends and coworkers may be disrupted contributing to an increased sense of social isolation and loneliness, which has been

associated with high rates of suicide, mental disorders, and mortality. Psychological stress has been recognized as a major factor contributing to earlier deaths among widowers due to biochemical changes (Parkes, 1972).

### Death of a Child

Parkes (1972) notes that the death of a child appears to produce greater emotional devastation for mothers than for fathers. Osterweis (1985) discusses the aspect of extreme guilt and anger, which may be experienced by bereaved parents due to the inherent need to prevent or actually save their child from the untimely death. Furthermore, the death of an adult child usually has a devastating and lasting impact on the physical and emotional health of aging parents (Osterweis, 1985). The surviving elderly parents may be forced to assume caretaking or financial responsibilities for the remaining grandchildren. Erikson's theory of generativity or grandgenerativity as a developmental stage of old age can be viewed as a reciprocal relationship from significant other loved ones involving caring and receiving care. A crisis may occur if the developmental sequence is severed when parents outlive their own children or grandchildren.

### Death of a Parent

Kalish (1987) attempts to explore the experience faced by the "older adult as a bereaved child" (p. 35). Parkes (1972) reports that the death of a parent does not produce an increase in health-related illnesses. However, it is not to be assumed that the death of a parent is less painful than other important losses. Residual feelings of guilt, anger, and hostility over unresolved issues may surface following the death of a parent. For some, a parent's death can be a severe blow to physical and mental health and stability.

### Death of a Sibling

As with the loss of a spouse, familial ties and relationships have extended for many years. Despite the level of past and present involvement, "the loss of a sibling, especially a younger sibling, remains a powerful reminder of one's own mortality" (Osterweis, 1985, p. 11). Depending on the level of emotional closeness or the degree of participation in daily activities prior to a sibling's death, feelings of vulnerability

to inheritable diseases and impending mortality are increased (Osterweis, 1985).

### Death of a Friend

Similar themes are present when a close friend dies, such as a decreased coping ability, anger, guilt, anniversary syndrome, visions of the deceased, and economic, legal, and health consequences. Doka's (1989) research on disenfranchised grief pays particular attention to the "friend as griever" experience (p. 77). He defines disenfranchised grief as "the grief that people experience when they incur a loss that is not or cannot be openly acknowledged, publicly mourned, or socially supported" (p. 4). Compared to the death of family members, the death of a friend is a powerful predictor and places the individual at an even greater risk for developing health problems. The frequency of lost friendships is similarly described by Kemeny et al. (1994) in the repeated bereavement situations among the HIV and gay community of men who have lost several close friends or lovers.

## MORTALITY AND GENDER

Widowers have higher mortality and suicide rates than widows (Stroebe & Stroebe, 1983) and appear to experience higher levels of psychological distress than women. Studies show an increase in the death rate among widowers over the age of 54 of almost 40% during the first 6 months of bereavement, indicating that the loss is experienced more severely by widowers than by widows (Parkes, 1972; Stroebe & Stroebe, 1983). According to one report, widowed men, regardless of age, are more susceptible to early death than their married counterparts (Osterweis, 1985). Furthermore, the effects of stress and poor self-care contribute to the high mortality rate among newly bereaved widowers (Gass-Sternas, 1995).

Stroebe and Stroebe (1983) explain gender differences and bereavement outcome in terms of a biological predisposition to specific health problems or diseases in which men and women are differentially susceptible. The evidence supports the notion that there is an interaction between biological, social, and psychological factors. Furthermore, "life events that appear to be harmful for the health of older men tend to be those involving disruption of social networks, i.e., bereavement and relocation" (Aldwin, 1990, p. 56). Aldwin (1990) studied the relationship between

egocentric stress (losses affecting the “self”) and non-egocentric stress (concern for others) on health status among aging male veterans and found that events causing a disruption in relationships such as losses related to bereavement or relocation were the most harmful and stressful events affecting their health.

Rogers and Reich (1988) discuss studies that report an excess in mortality following the first year after the loss of a spouse among widowers and also a higher death rate from physiological vulnerabilities, infectious diseases, accidents, and suicide than among widows. The difference may be reflected in the widow's perception of poorer health. Widowers may develop health problems over a longer period of time and may also tend to underestimate or underreport health difficulties immediately after the loss of their wives.

#### BEREAVEMENT, STRESS, AND SOCIAL SUPPORT

The death of a spouse eliminates the supportive characteristics of the marriage relationship in which roles were validated and assistance was shared among various tasks (Stroebe & Stroebe, 1983). Therefore, married people tend to have less strain than single people of either sex. Furthermore, it would imply that widows have less to lose in terms of roles than widowers due to the general idea that women carry the greater burden in the marriage role as housewife, mother, employed worker, or a volunteer outside the home. On the other hand, men have a greater tendency to remarry than women and are less prone to experience extreme role shifts. Social support, in general, and specifically in the form of various leisure or formal community supports, has been positively associated with psychological well-being and physical health, and in some cases serves as a buffer against the stress of bereavement and makes the experience less detrimental (Fitzpatrick, 1998; Fitzpatrick, Spiro, Kressin, Greene, & Bossé, 2001; Wheaton, 1985).

#### THEORETICAL PERSPECTIVES

Freud's (1917) psychoanalytic theory on mourning and melancholia focuses on the intrapsychic aspects of bereavement with regard to the concept of the libido that is attached or cathected to a lost loved object or person. Melancholia (abnormal or depressive illness) according to Freud results when the loss remains unconscious and the defense mechanism of

repression acts to inhibit these unconscious feelings from one's awareness or consciousness. Lindemann's (1944) theory focuses on acute grief and bereavement reactions addressing reactions to loss situations such as posttraumatic stress syndrome. Their ideas provide a reasonable explanation and understanding of the unconscious attachment mechanism and persistent tendency for the grieving individual to experience ongoing stress as a result of the intense work during the mourning and bereavement experience.

Bowlby (1969), Parkes (1972), and Marris (1978-1979) offer a perspective that combines psychoanalytic thinking and cognitively oriented theories. Bowlby postulates that attachment behavior is a survival mechanism for joining human beings to each other originating in childhood with the initial mother-child interaction. Grief and loss (bereavement) are essentially separation anxiety in which an unwanted separation from the deceased occurs, resulting in anxiety, protesting, and searching behavior. The relationship with the deceased is never completely severed. Furthermore, reactions to loss may be influenced by immunobiological or other stress-related factors depending on the individual and the circumstances. Parkes focuses his attention on cognitive restructuring to explain the bereavement process and employs three models: medical, cognitive, and cathartic. He attempts to explain the process of grief through medical classifications, and believes that the recovery period (cognitive restructuring) following a bereavement event for an individual must include the experience of pain, distress, and impaired functioning before recovery can be attained. Marris moves beyond attachment and instinctual behavior and proposes a cognitive theory of grief, which focuses on approach and avoidance tendencies and information processing in the bereaved as an attempt to restore predictability in one's environment.

Other important theories include the sociobiological perspective, which endeavors to address the aspect of kinship relationships in the grief process by making predictions about gender and age differences among family members (Littlefield & Rushton, 1986).

Ramsay's (1977) theory of grief includes the role of reinforcement, the environment, and situational factors such as social support. This ties in with the model of social support and stress-reduction proposed by Wheaton (1985). The present trend in the theoretical approach to bereavement is to encompass a broad and global psychological stress theory. This perspective may be more in line with specific loss events

(i.e., spouse, child, parent, sibling, friends, or other family members) and could be linked with an increase in stress and physical health problems. (See Fitzpatrick, 1998, for a detailed discussion.)

## SUMMARY

Bereavement represents a stressful life event, and frequently individuals are at a particular health disadvantage as evidenced by findings reporting high rates of psychological and physical disorders, mortality risk, and suicide. A broad theoretical perspective including aspects of psychoanalytic theory, cognitive theory, and sociobehavioral models including concepts of attachment, cognition, the role of kinship relationships, and the stress-reduction process was discussed as a conceptual framework for the study of bereavement, health, and survivors.

This review has practical importance for health care professionals who provide services to individuals and their family members in the community. The literature suggests that for bereaved individuals who have experienced the loss of a loved one, social supports may in fact serve as a buffer against the harmful impact of bereavement and thus reflect on physical and mental health. It is important to foster supportive relationships throughout the life span as the nature of relationships is often subjected to increasing loss of friends and loved family members. Social activities may provide an atmosphere to promote participation in an active lifestyle, thus preventing further health problems, isolation, or other maladaptive and self-destructive behavior. By broadening the definitions of loss, practitioners should identify the varying needs resulting from different types of bereavement events and engage in grief work tailored to specific supports that directly address these needs.

## BINGE DRINKING IN COLLEGE STUDENTS

---

Heavy drinking is an important factor in more than 100,000 deaths in the United States each year, including

**Table 1** Alcohol-Related Problems Among U.S. College Students

those resulting from motor vehicle crashes, falls, fires, drowning, assaults, homicides, and suicides. In addition, it is associated with a large percentage of non-fatal traumatic injury, thus making heavy alcohol use a major public health issue. Approximately one in five (21%) adults in the United States drank five or more drinks on one or more occasions in the past month, and almost half of all high school students who drank alcohol drank in this fashion. Young people tend to drink more heavily than older adults, and college students tend to drink more heavily than their same-age peers who do not attend college. As a consequence, students enrolled in 4-year colleges comprise one of the heaviest-drinking groups in America.

Heavy alcohol use among college students reflects a problem that is beyond simply a psychological, clinical, or developmental problem; it is one that is firmly rooted in the culture of college and in an environment that promotes a heavy-drinking lifestyle. Alcohol use and the problems that result from excessive drinking have been part of the American college experience since colonial days, although intensive study of this issue has not occurred until more recently. The first large-scale national survey of college student drinking was conducted by Straus and Bacon in 1950, and since that initial work more than 2,000 studies of college student alcohol use have been conducted. Unfortunately, few of these have involved rigorously conducted surveys of nationally representative samples of students and colleges. Studies of this nature can examine how drinking patterns are distributed and identify the factors that are associated with higher or lower levels of use. What is currently known from studies that meet criteria for sound scientific research is summarized in this entry.

#### RATES OF HEAVY DRINKING

The Harvard School of Public Health College Alcohol Study (CAS) was the first attempt to provide

a comprehensive description of college drinking using a nationally representative sample of colleges and students. This study found that a sizable minority of students nationally are binge drinkers—defined as five or more drinks in a row for males and four or more drinks for females on one or more occasions during a 2-week period. Two in five students (44%) attending college in the United States drink alcohol at this level or greater. The drinking style of many college students is one of excess and intoxication. Almost half of college students (48%) report that drinking to get drunk is an important reason for drinking; one in four (23%) drinkers drink 10 or more times in a month; and 3 in 10 (29%) drinkers report being intoxicated three or more times in a month.

This level of drinking has been found in four national CAS surveys between 1993 and 2001. Similar rates have also been reported by other national surveys, including the CORE survey, the Monitoring the Future Study, the National College Health Risk Behavior Survey, and the National Household Survey on Drug Abuse.

Alcohol use/abuse is a significant threat to the health and well-being of college students in the United States. The harms and secondhand effects of alcohol that students experience are directly associated with the amount of alcohol they or their peers consume. Alcohol-related harms include academic difficulties, psychosocial problems, antisocial behavior, physical injury, high-risk sexual behavior, overdose, and other risk taking, such as alcohol-impaired driving. Table 1 indicates that frequent binge drinkers are much more likely to report experiencing educational, health-related, interpersonal, and legal consequences than those who drink but do not binge.

The burden of college student drinking is high. More than 1,400 U.S. college students per year die from alcohol-related unintentional injuries, the majority in motor vehicle crashes. More than 2 million of the

8 million students drove a motor vehicle under the influence of alcohol, and more than 3 million rode with an intoxicated driver. Over 500,000 students were unintentionally injured while under the influence of alcohol.

The impact of college student alcohol abuse is not limited to the drinkers themselves. Students who attend schools with high rates of binge drinking experience a greater number of secondhand effects, including disruption of sleep or studies, property damage, and verbal, physical, or sexual violence, than their peers attending schools with low binge drinking rates. Recent estimates suggest that more than 600,000 college students per year are hit or assaulted by another student who has been drinking. In addition, residents of neighborhoods near heavy-drinking schools experience higher rates of noise disruptions, property damage, and police visits than those who live in neighborhoods surrounding schools with lower rates of heavy drinking and those who do not live near a college.

## HIGH-RISK STUDENTS

The study of alcohol use among college students has provided important insight into the factors associated with heavy drinking. Perhaps the most important finding of the CAS is that drinking behavior is not evenly distributed among different groups of college students. High rates of binge drinking exist among fraternity and sorority members, athletes, sports fans, highly social students, and those who engage in other risky behaviors. Underage students drink more heavily than their peers who are of legal drinking age, but they do so on fewer occasions. Some groups of students consume less alcohol or do not drink at all, in particular students of African and Asian descent; women; those with strong religious beliefs; and married, older, or nontraditional students.

Socializing is a major correlate of heavy drinking, and not surprisingly, students at the forefront of college social life use alcohol heavily. Students involved in fraternity and sorority life and athletics, two of the most prominent focus points of social life on campus, are among the heaviest drinkers. Beyond the high rates of binge drinking among fraternity and sorority house residents and members, fraternity parties also serve as a major source of alcohol for college students under the legal drinking age.

Where students live during college is an important factor in how much alcohol they consume. Rates of binge drinking vary according to the level of supervision

in their living environment and their proximity to other heavy drinkers. Among underage students, those living at home with their parents have the lowest rates of binge drinking. Among those living on campus, residents in housing designated as substance free (where students agree not to use alcohol and tobacco products) have the lowest rates of binge drinking. Students living off campus independent of their parents and students living in fraternity or sorority houses have the highest rates of binge drinking.

The transition from high school to college is a significant milestone in a young person's life. Entirely new social environments and the adoption of more adult roles as students become independent of their parents mark this change. This developmental perspective is an important factor in considering both risks for engaging in binge drinking and for prevention efforts. While many college students engage in binge drinking prior to their arrival on campus, a substantial number of students pick up binge drinking behavior in college. Student affiliations and their surrounding environments are important determinants of initiating drinking behavior in college.

## CONTRIBUTING FACTORS IN THE ENVIRONMENT

The intense study of college student drinking in the decade of the 1990s has resulted in significant gains in the understanding of this topic. However, the overwhelming majority of studies conducted have focused on factors that are proximal to the individual, such as personal and family drinking and other substance use history; social context; and individual beliefs, intentions, or expectations about alcohol use. The majority of these studies have been limited to single-school samples, or when several colleges are included, from opportunistic rather than representative samples. Studies of this nature are unable to examine features of the environment that may contribute to alcohol use and problems because these factors are held constant. As a consequence, far less attention has been given to environmental factors that may influence college student drinking. These include state, local, and college-level laws; policies regarding the sale and consumption of alcohol; and the enforcement of these standards.

Rates of binge drinking vary dramatically by college (ranging from 1% to 76%), by region of the country (higher in northeastern and north-central states,

lowest in western states), and importantly, by the sets of policies and laws governing the sale and use of alcohol at the college, city/town, and state levels. Understanding the patterns of drinking by different groups of students can help identify potential intervention strategies to reduce alcohol consumption, and, in turn, the harms that result from heavy consumption. Interestingly, features of the environment such as residential settings, low prices, and a high density of alcohol outlets are significantly related to the initiation of binge drinking in college. This combination of factors in the environment that promote heavy drinking is referred to as a “wet environment.”

A consistent finding of the CAS has been that the price students pay for alcohol is an important factor in their drinking. Low price and very easy access to alcohol are strong correlates of underage drinking. Student underage drinking and binge drinking are sensitive to the price of alcohol and may be reduced by efforts to increase the unit price of alcohol. Students who pay a higher price for alcohol are less likely to make the transition from abstainer to moderate drinker and from moderate drinker to heavy drinker.

Some campus, local, and state policies that target alcohol use are associated with less drinking and binge drinking among college students. Students attending colleges that ban alcohol are less likely to binge drink and more likely to abstain from alcohol. As a result, fewer students at schools that ban alcohol experience secondhand effects of the drinking of others than students at non-ban schools. At schools that allow students some access to alcohol, substance-free residences are associated with less alcohol use and fewer secondhand effects of alcohol.

State and local alcohol policies are also associated with drinking behavior among college students. Strong state and local drunk driving policies targeting youths and young adults significantly reduce drinking. The national Minimum Legal Drinking Age (MLDA) law in the United States appears to be an effective deterrent against heavy drinking and its negative consequences. The enactment of this law was associated with a significant decrease in traffic fatalities involving drivers 18 to 20 years of age. Since 1975, the MLDA of 21 has saved an estimated 20,000 lives in collisions involving drivers in this age group. Alcohol-involved motor vehicle crashes are a leading cause of death and serious injury for college students. Beyond the MLDA law, other restrictions on sales to and possession by persons under the legal drinking

age are associated with less drinking by underage college students. Underage students in states with extensive laws restricting underage and high-volume drinking are less likely to drink and to binge drink.

## FUTURE DIRECTIONS

A significant amount of time, energy, and money has been devoted to the issue of college student drinking by college administrators and prevention planners. The activity to date has focused on efforts to educate drinkers or on providing treatment and judicial sanctions for the most serious offenders. Features of the environment that promote heavy alcohol use, such as college drinking traditions, lax policies or enforcement, easy accessibility to cheap alcohol, and gaps in service networks, have received far less attention as prevention efforts.

While researchers have learned a great deal about describing the problem of college student binge drinking, and intensive efforts have been undertaken to address the problem, very little progress has been made in reducing alcohol consumption in this population. Unfortunately, despite the high rate of problems experienced by students who engage in frequent binge drinking, very few of them recognize their problems on their own. Less than one quarter of frequent binge drinkers think they ever had a problem with alcohol and only 13% of this group think they are heavy or problem drinkers. As a result, among this heaviest-drinking group less than 3% have sought help for their drinking.

These findings suggest that additional efforts may be necessary. The findings of the CAS strongly suggest that limiting access to alcohol is a promising strategy to reduce the harms and secondhand effects. Building individual-level resistance skills may be an ineffective or incomplete strategy in the face of a heavy-drinking culture and promotional activities by national and local alcohol industries to entice college students to drink heavily. Given the limited success of efforts to date and the mixed evidence of efficacy from the most intensely studied individually focused interventions, further efforts might be directed toward limiting the exposure of college students to aggressive marketing or increasing counter-advertising, reducing the easy access to low-priced alcohol, and limiting the high density of alcohol outlets. These strategies, often referred to as “environmental management,” represent a promising avenue for prevention of alcohol-related problems. A recent expert panel convened by the

Substance Abuse and Mental Health Services Administration (SAMHSA) summarized the findings in this area and recommended that interventions addressing these areas were feasible and effective.

Efforts to reduce student alcohol use and abuse may require coalitions of people representing various interests and strong grassroots organizing. If and when colleges or those who live in college communities implement these types of interventions to reduce alcohol use and abuse among students, they should be rigorously evaluated to determine their effectiveness.

## BIOFEEDBACK

Biofeedback is a widely used method for teaching people voluntary control of various physiological functions by providing instantaneous information about the status of the person's physiological activity. Feedback usually is given in the form of visual and/or auditory signals derived from physiological recording devices. People can use biofeedback to obtain voluntary control over their bodies. Biofeedback methods have been successfully applied to treating a wide variety of ailments, including headache and other chronic pain conditions, hypertension, vasospastic diseases, incontinence, and insomnia (Schwartz & Andrasik, 2003).

Biofeedback is easy to learn, with competent practitioners located in or near most communities. Equipment to perform it is readily available at reasonable cost (from about \$300 for clinical units to about \$3,000 for units with research capabilities). Most patients find it intriguing and enjoyable, and compliance tends to be at least as high as with various medical treatments for chronic diseases. Special software programs have been written for children, where biofeedback is structured as a video game in order to maintain interest in the process.

### CARDIORESPIRATORY BIOFEEDBACK

Biofeedback can be successfully used to teach people to control various cardiovascular and respiratory functions, for example, blood pressure, heart rate and heart rate variability, blood flow to specific body organs, and respiration rate and resistance.

*Surface temperature.* The most widely studied and commonly used cardiovascular biofeedback method has

been thermal biofeedback. In this method, a sensor (usually a thermistor) is attached to a target organ (most frequently one of the extremities), and people are given immediate feedback that is sensitive to a tenth of a degree Fahrenheit or less. Changes in local body temperature usually reflect changes in blood flow, mediated by dilation or constriction of blood vessels in the area.

Teaching people to warm their extremities can be helpful for Raynaud's disease, a problem involving spasms in the blood vessels to the extremities that can lead to severe discomfort and susceptibility to infection. Preliminary controlled research has shown that finger temperature biofeedback also can reduce blood pressure among individuals with hypertension.

*Heart rate.* A number of investigators have used biofeedback to teach people to increase or decrease their heart rates by direct heart rate biofeedback. This method can decrease the heart rate responses to stressful or painful stimuli, and decrease associated pain perception and anxiety.

*Blood pressure.* Direct biofeedback for blood pressure levels has also been attempted, using devices that can measure beat-to-beat blood pressure, thus assessing immediate changes. A controlled trial among hypertensive patients showed that systolic blood pressure decreased more (about 10 mm Hg) with biofeedback than with a control treatment. A recent controlled trial among patients with "white coat hypertension" (i.e., high blood pressure in the physician's office but not in other settings) found that blood pressure decreased by 23/11 mm Hg in the treatment group, with no change in the control group.

*Heart rate variability.* A relatively new biofeedback method involves teaching people to increase heart rate variability. The cardiac system, like most biological systems, demonstrates constant variation when in a healthy (or homeostatically balanced) state. When successive interbeat intervals are plotted against time, a pattern of regular oscillations has been found in several frequency bands (Task Force of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology, 1996). It has long been postulated that a pattern of high-amplitude oscillations across frequency bands and of successive interbeat heart intervals that are less predictable (or more "chaotic") is associated with health, fitness, survival, and adaptability.

Due to resonant properties of the cardiovascular system, high amplitudes of heart rate oscillations can be generated at specific frequencies, sometimes as high as 60 beats/minute peak-to-trough among young healthy adults, when people breathe slowly, at frequencies associated with nonrespiratory reflexes. Particularly high amplitudes can readily be produced at approximately 0.1 Hz (6 cycles per minute) by breathing at this rate, a rhythm that reflects baroreflex activity. The baroreflexes are important modulatory reflexes by which increases in blood pressure induce decreases in heart rate and vascular tone, while decreases in blood pressure induce increases in these functions. Respiration also causes an oscillation in heart rate, known as respiratory sinus arrhythmia. This rhythm usually is at a higher frequency (0.15-0.4 Hz). Recent research has indicated that biofeedback training to increase amplitude of heart rate variability causes people to breathe slowly (indeed, at approximately 0.1 Hz), thus producing robust increases in gain of the baroreflexes. In this process, biofeedback causes people to breathe at about six breaths per minute, thus producing higher-amplitude oscillations in heart rate, that are associated with both respiration and oscillations in blood pressure. Resonance occurs at this frequency, leading to very high amplitudes of heart rate variability.

This method also appears to have clinically significant effects on asthma. Case studies have suggested that it also may be useful for treating other disorders involving autonomic hyperreactivity.

*Respiratory rate.* Slow breathing has long been a component in various Eastern meditative practices that produce profound psychophysiological effects, including a sense of "centeredness" and clinical effects similar to those described for heart rate variability biofeedback. Cultivated slow breathing rates (often at about 6 cycles/minute, as in heart rate variability biofeedback), included in various yoga exercises and/or respiratory biofeedback, have been found helpful for treating hypertension, asthma, and anxiety. When applied this way, the effects of this method are very similar to those of biofeedback training for increasing heart rate variability.

*Other respiratory parameters.* Direct continuous biofeedback of respiratory impedance using oscillation pneumography has been successfully used to improve respiratory function in asthma. Biofeedback

training to increase end-tidal CO<sub>2</sub> has been successfully used in treating several cases of panic disorder.

## BIOFEEDBACK FOR SKELETAL MUSCLE ACTIVITY

Biofeedback for the muscles is called surface electromyography (SEMG). As our muscles contract, getting shorter and moving our bones or the skin on our face, the muscle fibers that cause this movement “depolarize,” giving off bundles of electrical energy that can be picked up using electrodes placed over these muscles. This energy is displayed on a computer screen and may then be “fed back” to the individual by converting it to audio tones, time-series line graphs, or other forms of visual display.

John Basmajian (1962) is sometimes referred to as the father of EMG biofeedback. He used biofeedback from concentric needle EMG recordings to teach a person how to control the “neuromuscular” system down to a small nervous system component called the “single motor unit.” Muscles consist of hundreds of motor units. For example, the large bulging muscle of the upper arm, the biceps, contains thousands of muscle fibers. These fibers are organized into bundles of approximately 100 muscle fibers, with each bundle controlled by a single neuron from the brain or spinal cord.

Edmund Jacobson used SEMG biofeedback as an assessment device to assist patients in healing themselves through a technique called “progressive relaxation.” Here the patient was trained to recognize and control subtle amounts of muscle tension by systematically tensing and releasing specific muscle groups throughout the body, with progressive decreases in the amount of tension applied. In this clinical context, SEMG biofeedback was used to provide precise information about tensing and releasing the muscles, but not yet as a training method. Jacobson and his followers taught patients to relax their muscles in everyday life as well as in the treatment room, and found that they thereby helped patients to control a variety of symptoms including headache, muscle aches, gastrointestinal symptoms, cardiovascular symptoms, and anxiety.

Later, Elmer Green applied SEMG feedback to assist in relaxation, and Thomas Budzynski et al. conducted the first scientifically based clinical study to demonstrate the clinical effectiveness of using SEMG biofeedback in treating tension headaches.

Over the years, SEMG biofeedback training has been used adjunctively to assess and treat a variety of medical disorders, including stroke, subvocalizations during reading, temporomandibular joint disorders, neck pain, shoulder pain, back pain, hip dysfunction, knee pain, repetitive strain injury, chiropractic subluxations, pelvic pain, and urinary and fecal incontinence. This research has recently been reviewed (Cram & Kasman, 1998; Kasman, Cram, & Wolf, 1998).

The use of high-speed computers to analyze SEMG data has demonstrated that the energy spectra of muscle activity gives considerable information about muscle fatigue and may help to describe back pain. Linear arrays of SEMG electrodes can be used to visually track the depolarization of the muscle fiber along its length. Periodic rest during work has been found to be very important for muscle health. Cram (1990) has developed a clinical procedure called “muscle scanning,” which allows the clinical practitioner to visualize patterns of muscle tension or bracing throughout the head, neck, and torso. A consensus paper on the use of SEMG has recently been published (Hermens et al., 1999). The clinical applications for this tool will continue to develop as the future unfolds.

## NEUROFEEDBACK

Neurofeedback (NF) is a kind of biofeedback in which the physiological event targeted for operant change involves central nervous system activity. In recent years, NF typically has involved electroencephalographic (EEG) activity, and the goal of the NF training is a clinical one. For example (and this will be expanded below), since it is known that increased low-frequency EEG activity (theta) and decreased higher-frequency activity (beta) are typical EEG correlates of attention deficit disorder (ADD), the most well known protocol for treating ADD with NF involves operant training to increase the beta-to-theta ratio.

Many of the earliest studies of NF had no aims other than the theoretically important aim of showing that nontrivial changes in neural events could be made by operant conditioning. Joe Kamiya devised the only protocol for relaxation approved by the Food and Drug Administration, increased alpha generation. Abraham Black studied the relationship of hippocampal theta training to learning and to motor processes.

On the other hand, even pioneering researchers in this area saw the clinical potential of the NF method.

Wolpaw et al. (2000) have recently developed NF-based means for allowing communication to and from paralyzed patients previously unable to communicate. Rosenfeld's (1995) group has demonstrated that operant control (NF) of cortical somatic sensory evoked potentials (EPs) can profoundly affect the pain thresholds in rats. The NF training had an effect equivalent to a moderate dose of morphine. This approach, however, has had minimal follow-up in human clinical patients.

Another pioneering effort in NF has been the work of Barry Sterman, who noted that by training patients with convulsive disorders to increase the amount of 12- to 14-Hz activity on the scalp area overlying the sensorimotor cortex, he could greatly reduce their seizure incidence. This activity (also called SMR for sensorimotor rhythm) is also seen in cats. To show that the therapeutic effect in human patients was not simply a placebo or transference cure, Sterman demonstrated that cats trained to generate increased SMR show much greater resistance to seizure elicitation by the strongly epileptogenic substance monomethyl hydrazine. There were fewer seizures in the trained cats, the elicited seizures were less severe, and the seizure onset times from exposure to the drug were longer. Here, clearly, was an NF application suitable for clinical trials, but again, for some reason, this effective NF protocol, the only one until very recently in which control studies were available, has been largely ignored by the neurology and psychiatry communities that treat persons with epilepsy.

The most influential and best-known NF protocol is that developed by Lubar and associates for the treatment of ADD. Lubar, Monastra, and colleagues have established beyond question that ADD is associated with EEG slowing, that is, an abnormal increase in slow-wave EEG activity and an abnormal deficiency of high-frequency beta activity. With this sound empirical and conceptual foundation, they developed and repeatedly tested successfully an NF protocol known as the beta-theta or Lubar protocol for ADD. There have been dozens of independent clinical replications, and a controlled study has recently been reported (Monastra, Monastra, & George, 2002). This study compared therapeutic effects of Ritalin, the standard medical treatment for ADD, with the Lubar protocol in treatment of ADD. It was found that both therapies affected ADD symptoms, but that the effects of Ritalin were absent when the substance was cleared 24 hours after administration. On the contrary,

the effects of the Lubar protocol were long lasting. In particular, the effects of the Lubar protocol affected the EEG so as to normalize it. Ritalin did not have these effects on the core neural sign of ADD, the cortical slowing.

Rosenfeld, Baehr, and colleagues (Rosenfeld, 2000) have presented a clinical protocol and several case reports showing that NF can be used to produce clinically beneficial effects on mood disorders. The conceptual and empirical foundation for the protocol is as follows: Early research by Leonide Goldstein and later findings by Richard Davidson and colleagues had repeatedly shown that negative affect is associated with more right than left frontal cortical alpha activity, an *inverse* index of activation. Normal or positive affect shows the reverse frontal cortical asymmetry of activation. Thus, the "asymmetry protocol" developed by Rosenfeld reinforces depressed subjects for reversing the pathological to the normal activation asymmetry pattern.

## CONCLUSION

Biofeedback has been successfully applied as an aid to teaching people to control various physiological functions. Although officially listed as a method of "complementary" medicine by the National Center for Complementary and Alternative Medicine of the National Institutes of Health, its effects on several disorders have been sufficiently well established for the method to have become part of standard clinical practice. Its strong effects also make biofeedback a useful educational tool for teaching about the body and improving human performance.

## BLOOD PRESSURE AND HYPERTENSION: MEASUREMENT

---

Hypertension (high blood pressure) is a major risk factor for cardiovascular morbidity and mortality. As such, the accurate measurement of blood pressure (the pressure in the blood vessels associated with the flow of blood with each heart beat) and the assessment of hypertension are essential to the health of the population. In the 175 years since Poiseuille described the use of the mercury manometer to measure blood pressure, the accurate assessment of blood pressure has remained a challenge to clinicians and researchers alike (Jones, Appel, Sheps, Rocella, & Lenfant, 2003;

Poiseuille, 1828). The early assessments required invasive measures to attach an artery to the recording device, severely limiting the routine assessment of blood pressure. However, recent advances now permit blood pressure to be recorded on a beat-to-beat basis in ambulatory subjects thus allowing blood pressure to be linked to environmental, situational, and behavioral factors (Parati, Omboni, & Mancia, 1995).

This entry briefly describes the measurement of blood pressure and the assessment of hypertension in both the clinical and research contexts. The physiological basis of blood pressure is described first, then the clinical basis for the assessment of hypertension. Next, an overview of the measurement of blood pressure in the research and ambulatory settings is provided. Finally, new indices derived from blood pressure measurements including pulse pressure and blood pressure variability and their associations with end-organ damage and cardiovascular disease risk are presented.

### PHYSIOLOGICAL BASIS OF BLOOD PRESSURE

The maintenance of blood pressure (BP) is one of the primary functions of the organism (Julius, 1988). Whereas the exact determinants of BP cannot be assessed noninvasively, noninvasive measures may provide important information for clinicians and researchers. A simplified approach to understanding the determinants of BP has been suggested that divides the determinants into physical and physiological factors (Berne & Levy, 1997). Physical factors include blood volume and arterial compliance (the elasticity of the arteries), whereas physiological factors include cardiac output (the amount of blood pumped by the heart in a given amount of time such as 1 minute) and peripheral resistance (the resistance of the peripheral vasculature to the flow of blood). Blood volume is a major determinant of long-term BP regulation and thus explains the use of diuretics as a first-line treatment for hypertension (Chobanian and the National High Blood Pressure Education Program Coordinating Committee, 2003). Cardiac output (CO) is a function of heart rate (HR) and stroke volume (SV: the amount of blood pumped with each cardiac contraction) such that  $CO = HR \times SV$ . Mean arterial pressure (the average pressure in the arteries over some time interval) is a function of CO and peripheral resistance. The autonomic nervous system is intimately involved in the control of BP such that changes in BP may be due to various combinations

of parasympathetic (i.e., HR), beta-adrenergic (i.e., SV), and alpha-adrenergic (i.e., peripheral resistance) activity. Recent research also points to the role of both central and peripheral nitric oxide (a biologically active molecule associated with, among many other things, the dilation of blood vessels) in BP regulation (De Meyer & Herman, 1997).

## CLINICAL ASSESSMENT OF HYPERTENSION

Normal BP, assessed on the basis of systolic (pressure during the cardiac systole or contraction: SBP) and diastolic (pressure during the cardiac diastole or relaxation: DBP) blood pressure, is considered to be < 120 mm Hg SBP and < 80 mm Hg DBP. Prehypertension has recently been defined as 120-139 mm Hg SBP or 80-89 mm Hg DBP. Stage 1 hypertension is defined as 140-159 mm Hg SBP or 90-99 mm Hg DBP, whereas Stage 2 hypertension is defined as > 160 mm Hg SBP or > 100 mm Hg DBP. Each of these levels of classification, in combination with other factors, is associated with specific risks and treatment recommendations (Chobanian et al., 2003). However, it should be noted that there is a largely linear dose-response relationship between BP levels and cardiovascular disease risk that extends across the range of BP levels (Douglas and the Hypertension in African Americans Working Group, 2003). Moreover, recent statements suggest that individualized target BPs and risk assessments may be necessary to achieve adequate BP control in individuals from certain populations including African Americans (Douglas et al., 2003).

## MEASUREMENT OF BLOOD PRESSURE IN CLINICAL AND RESEARCH SETTINGS

Most methods of measuring BP rely on intermittent measurements. These methods include the auscultatory method based on Korotkoff sounds and the oscillometric method based on the amplitude of cuff pressure oscillations (Shapiro et al., 1996). The auscultatory method is based on the perception of the sounds of the heart valves opening and closing at different points in the pressure gradient (the so-called Korotkoff sounds), whereas the oscillometric method measures the difference between pressures assessed by an inflatable cuff during the systole and diastole.

These methods can be used in both clinical and research settings. Moreover, these methods can be used for the assessment of ambulatory 24-hour BP.

Recent techniques for the continuous assessment (beat-to-beat) of BP include the tracking cuff system (Shapiro, Greenstadt, Lane, & Rubenstein, 1981), tonometric, and vascular unloading methods (Penaz, 1973). Whereas the absolute values of these latter methods have been questioned, they represent a major advancement in the quest to understand behavioral influences on BP as they allow the linking of specific, relatively short timeframe behaviors to coincident BP. Similar linking can be done with 24-hour intermittent measures but with less temporal resolution (Jacob et al., 1999). Importantly, the use of 24-hour BP has been shown to be critical for the assessment of hypertension status particularly when “white coat hypertension” (a condition in which a patient’s BP is elevated in the doctor’s office or clinic but is normal elsewhere) is present (Chobanian et al., 2003).

## OTHER INDICES DERIVED FROM BLOOD PRESSURE RECORDINGS

Whereas cardiovascular disease risk is commonly assessed in terms of SBP and DBP, other indices derived from BP recordings have been shown to be independent risk factors for end-organ damage, morbidity, and mortality. For example, pulse pressure (the difference between SBP and DBP), a measure of arterial compliance, has been shown to be an independent risk factor for morbidity and mortality, especially in older persons (Franklin, Khan, Wong, Larson, & Levy, 1999; Glynn, Chae, Guralnik, Taylor, & Hennekens, 2000). Importantly, BP variability including 24-hour standard deviation, the morning rise in BP or night-time fall of BP, and the periodicities present in 24-hour beat-to-beat BP recordings has been shown to be an independent risk factor for cardiovascular morbidity and mortality (Parati et al., 1998; Parati & Lantelme, 2002).

Factors that influence BP variability are being explored with behavioral factors prominent. In addition, the implications of BP variability for shear stress (the stress on the blood vessels caused by the ebb and flow of blood), plaque rupture (the breaking away from the wall of the blood vessel of a fatty deposit), and nitric oxide release are being investigated.

## SUMMARY

In summary, the accurate measurement of BP is crucial for the assessment of hypertension. Recent advances in the measurement of BP, particularly

ambulatory measurement, promise to enhance the prevention, diagnosis, and treatment of BP-related diseases and explicate the role of behavioral factors in BP regulation.

## BLOOD PRESSURE AND HYPERTENSION: PHYSICAL ACTIVITY

---

Blood pressure changes in response to physical activity include immediate responses during the activity, changes that last for a few hours after a bout of sustained aerobic exercise, and longer-term changes that are observed beginning a few weeks after sedentary individuals start a regular exercise training program. Regular physical activity is now recommended by hypertension experts and public health authorities for preventing the development of hypertension and for helping to reduce elevated blood pressure in individuals who have already been diagnosed with mild to moderate levels of hypertension. Both aerobic and strength-training type exercises can be safe and beneficial if performed within recommended guidelines.

## OBSERVATIONAL EVIDENCE

Some of the evidence about the importance of physical activity for cardiovascular health and blood

pressure regulation comes from observing large numbers of people for long periods of time to determine what distinguishes those who go on to develop hypertension from those who do not. In a study of Harvard University alumni, men who reported regular participation in vigorous sports 1 to 2 hours a week were much less likely to develop hypertension as they grew older. Another important observational study involved thousands of people who had undergone fitness testing at the Aerobics Center in Dallas, Texas. Investigators found that those who had lower levels of physical fitness (and therefore probably engaged in less regular physical activity and exercise) were much more likely to develop hypertension. Studies conducted in other countries with individuals of different genetic backgrounds have similarly found that people who are more physically active and/or with higher levels of physical fitness are likely to have lower blood pressure and are less likely to be diagnosed as hypertensive. These observations have encouraged investigators to learn how physical activity helps regulate blood pressure and whether exercise can be used as a non-pharmacological treatment for people whose blood pressure is too high.

#### IMMEDIATE RESPONSE OF BLOOD PRESSURE DURING PHYSICAL ACTIVITY

With the initiation of rhythmic muscle contractions in aerobic physical activity, such as walking, jogging, or cycling, many changes occur in the cardiovascular system to provide blood and oxygen to the working muscle as well as sustain the other body organs. In healthy individuals, systolic blood pressure rises rapidly, then levels off, and diastolic pressure changes very little. Following a bout of sustained aerobic activity, the blood pressure falls to a lower level and remains lower than the usual resting level for several hours.

Resistance type exercise causes different cardiovascular responses. With the strain of weight lifting or other resistance activity, blood pressure rises quickly, even if the work does not require great effort. For this reason, individuals who have cardiovascular disease or elevated blood pressure should seek medical advice before starting resistance exercise training. With regular resistance training, the immediate blood pressure response is lessened and the short-term changes do not cause sustained high blood pressure.

#### RESPONSE OF BLOOD PRESSURE TO SUSTAINED EXERCISE TRAINING

More than 50 studies have now been reported on the effects of weeks or months of exercise training on blood pressure. Many, but not all, of the studies have found a beneficial effect. Some of the studies have been conducted in a manner that demonstrated the blood pressure-lowering effect occurs even without changes in weight, diet, or other lifestyle factors.

Recently, several studies have used meta-analysis, a method of pooling the results of previously published studies, to determine the amount of blood pressure change that occurs with aerobic exercise and what factors may affect the amount of change that is observed. These meta-analyses concluded that regular aerobic (endurance) exercise lowered blood pressure, even if there was no weight change. On average, the exercise used in experimental studies lowered systolic blood pressure by about 3 to 4 mm Hg and lowered diastolic blood pressure about 2 to 3 mm Hg. Individuals within the studies experienced a wide range of blood pressure change, and some studies found greater changes than others. The meta-analyses compared subgroups of individuals across the studies to look for predictors of greater blood pressure effects. These analyses suggest that both normal-weight and obese individuals benefit from exercise training but that those who are already hypertensive compared with normotensives, individuals of African and Asian origin as compared with those of European ancestry, men as compared with women, and middle-aged as compared to older individuals may experience the largest blood pressure changes in response to aerobic exercise. More research is needed to confirm these possible differences between subgroups.

Another important question is what type of exercise is best and how much exercise is necessary for benefit. These questions have not been fully answered. The exercise used in successful experimental programs thus far included brisk walking, jogging, cycling, aerobic dance, and swimming. Almost all the programs studied have been of sufficient intensity to increase cardiovascular fitness, with the exercise performed three to five times per week for at least 20 to 30 minutes duration, with heart rate at 50% to 80% of the maximum. Only a few studies have examined the effects of resistance training on blood pressure. These studies have generally shown that regular participation in resistance training type activity can lower resting blood pressure and does not lead to blood pressure increases.

## HOW DOES PHYSICAL ACTIVITY LOWER BLOOD PRESSURE?

The mechanisms for blood pressure reduction by aerobic exercise are still not fully understood. Exercise is a complex set of behaviors, causing different effects depending on the specific type of activity, the intensity or effort with which it is performed, the duration of the exercise training sessions, and the frequency of the exercise. Experts believe that aerobic exercise may help reduce blood pressure through a variety of changes, including decreases in the volume of fluid retained in the body, vasodilatation, changes in the input to pressure receptors in the cardiovascular system, and reducing sympathetic nervous system activity.

## PHYSICAL ACTIVITY AND HYPERTENSION PREVENTION AND TREATMENT

While the average amount of blood pressure change that occurs with regular exercise may seem small for an individual who would like to avoid taking medication for hypertension, some individuals will experience greater blood pressure lowering, especially those who adjust their diets and lose weight in addition to increasing their physical activity. Even without weight changes, if many more children and adults in the population adopted healthy physical activity consistent with current public health guidelines, many thousands of cases of hypertension would be prevented. It is also important to note that regular physical activity and exercise provide many other cardiovascular risk reduction effects and other health benefits. Thus, regular physical activity and exercise are important for health and quality of life of all individuals, even if they do not experience significant changes in blood pressure.

—Patricia M. Dubbert

## BLOOD PRESSURE, HYPERTENSION, AND STRESS

Essential hypertension or high blood pressure affects almost 50 million Americans and is a major contributor to mortality from cardiovascular disease, the leading cause of death among Americans. Hypertension increases risk for a variety of medical conditions, including myocardial infarction, stroke, congestive heart failure, peripheral vascular disease, hypertensive retinopathy, left ventricular hypertrophy, kidney failure, and cognitive impairment. This disease disproportionately affects the poor, the elderly, and African Americans. Prevalence of hypertension is 40% higher among African Americans compared to White Americans, and African Americans develop the disease at an earlier age, experience a more severe course, and are at higher risk for left ventricular hypertrophy, stroke, renal disease, and hypertension-related mortality than all other ethnic groups in the United States.

There is general consensus that hypertension is a multiply determined disease with no known specific cause. However, beginning with Franz Alexander's early psychodynamic theory, considerable scientific attention has been given to understanding how psychosocial stress and personality characteristics might contribute to hypertension risk.

The notion that stress should be implicated in enhanced hypertension risk has heuristic appeal; however, efforts to demonstrate a causal role for stress in hypertension have been unsuccessful for several reasons. First, sustained high blood pressure is likely the result of several etiologic factors, including genetic, biomedical, socioecologic, behavioral, and psychological risk factors, all of which exert their effects in interaction and over time. Second, there is substantial evidence that hypertension is most likely to develop in persons who are genetically predisposed to this disease and less likely to develop in those who lack this biological predisposition, even in the presence of other

environmental and lifestyle risk factors. For example, studies in both animals and humans suggest that genetic vulnerability and sodium sensitivity may be major pathways of risk for stress-induced hypertension, such that individuals who are sodium conservers (i.e., have a tendency to retain sodium) may be more vulnerable to the cardiopathogenic effects of stress than those who are more efficient sodium excretors. Third, researchers generally agree that stress is best thought of as a general risk factor that can contribute to a variety of medical and psychological disorders, but is not a specific causal factor in any disease or disorder. Therefore, the contribution of stress to risk for hypertension must be considered in the context of genetically mediated predispositions, and the host of other co-occurring and interacting factors noted above.

This entry provides a brief review of the evidence linking psychosocial stress to essential hypertension in terms of (1) stress exposure, (2) stress appraisal and coping, and (3) the biobehavioral stress reactivity hypothesis. The entry also reviews results of studies of behavioral treatments for essential hypertension.

## GENERAL MODELS OF STRESS AND DISEASE

Various models of stress have been formulated to explain how various sources and types of stress translate into symptoms of disease and dysfunction. Modern models of stress and disease propose complex relationships between *stress exposure*, which involves experience with episodic and chronic environmental demands, and *stress response*, which involves emotional, physiological, and behavioral responses to the appraised stressor, and their reciprocal relationships. These models also recognize the importance of several factors that moderate or mediate the experience of stressors and the development of symptoms and illnesses, including *stress appraisal*, which involves estimating the relative threat of stressors by weighing demands against available resources; *social resources for support*, which may either protect or reduce the detrimental effects of a high stress burden; *psychosocial resources* such as self-efficacy and self-esteem; and *stress coping*, which involves psychological and/or behavioral efforts to manage the appraised stressors.

## MODEL OF STRESS AND HYPERTENSION

In the specific case of hypertension, a stress-mediated model for this disease would suggest that

(1) greater exposure to or burden of psychosocial stresses will enhance risk for developing essential hypertension in those who possess biological predispositions for this disease; (2) the effects of greater stress burden will be exacerbated by socioecologic factors, such as disproportionate burden of stress due to family and job stresses, socioeconomic deprivation and discrimination, and detrimental lifestyle factors, such as obesity, high salt/fat diet, smoking, alcohol abuse, and a sedentary lifestyle; (3) stress burden will be mediated through cardiovascular hyperreactivity, which is hypothesized to result in sustained high blood pressure by dysregulating blood pressure control mechanisms; and (4) the effects of stress exposure will be moderated by psychological and social factors such as social supports, and emotional regulation, especially anger suppression, hostility, and repressive coping.

## STRESS EXPOSURE AND HYPERTENSION

### Stressful Environments

Stressful environments have the potential to significantly affect blood pressure. Multiple types of threatening environments, such as wars, low-income urban residential areas, and noisy workplaces, have been related to prolonged increases in resting blood pressure. One widely cited 20-year prospective study demonstrated that exposure to normal daily living in Western society compared to secluded monastic living is associated with age-related increases in blood pressure over 20 years (Timio et al., 1988).

Environments that contain recurrent social conflict also are associated with marked blood pressure increases. For example, researchers studying the effects of crowding on prison inmates found that inmates who lived in dormitories had higher resting blood pressures compared to inmates who lived in single cells and that blood pressure levels changed when inmates were transferred to and from single cells to dormitories (D'Atri, Fitzgerald, Kasl, & Ostfeld, 1981).

### Stressful Cultures

There is evidence that the chronic stress of social change and competition for resources is a factor affecting blood pressure in modernized countries, with a strong graded relationship between population blood pressure and level of industrialization. However, stresses due to modernization and acculturation do not operate independently on blood pressure, but are associated

with changes in physical activity, obesity, dietary intake, social integration, and social support, all of which also contribute to enhanced risk for hypertension.

### Occupational Stress

Karasek and colleagues (Karasek, Baker, Marxer, Ahlbom, & Theorell, 1981) developed one of the first models linking high job strain with increases in ambulatory blood pressure. High job strain, defined as high work demands and low decisional latitude, has consistently been linked with higher resting blood pressure at work, and this effect generalizes outside of work and during sleep. These job strain effects have been observed only when ambulatory blood pressure monitoring (ABPM) is used. Other risk factors, such as alcohol consumption, age, and gender, have been shown to moderate job strain, such that those in high-strain jobs evidence higher resting blood pressure if they are older, consume alcohol, and are men. Surprisingly, high-strain jobs appear to have little effect on blood pressure in women, suggesting that there may be important gender differences in the appraisal, experience, and/or physiological reactions to job demands.

### Racism and Discrimination

African Americans have 2 to 4 times higher rates of hypertension than other ethnic groups in the United States. This greater burden of morbidity and mortality from this disease is attributable to several factors, including genetic history, greater tendency toward sodium retention, disproportionately higher rates of obesity (particularly in women), and lower intake of calcium, potassium, and magnesium. Socioenvironmental stressors are also important contributors to disproportionate risk. A disproportionate percentage of the African American population live under conditions of economic deprivation, with concomitant greater exposure to multiple stresses (e.g., crime, heightened vigilance) and inadequate material and psychosocial resources (e.g., health care). Exposure to racism and discrimination are significant contributors to this stress burden and have been linked specifically to enhanced risk for hypertension (Williams & Neighbors, 2002).

While the amount and type of racism and discrimination in the United States may have changed in recent years (i.e., a shift from overt to more covert forms of discrimination), exposure to discrimination continues to create a psychologically threatening and undermining

environment and limits access to resources and life opportunities. These psychosocial and environmental stresses can also lead to the development of negative coping styles that can further enhance risk for hypertension, such as use of illicit drugs and alcohol, excessive eating, smoking, and unresolved anger and hostility.

### Lifestyle Incongruity

Another source of stress that has been linked to enhanced risk for hypertension is lifestyle incongruity, which involves maintaining a lifestyle that exceeds economic resources. Studies have found higher resting blood pressures and higher rates of hypertension in African Americans with high lifestyle incongruity (Dressler, 1991). However, to date, this relationship has not been observed in other ethnic groups and may be indirectly related to the effects of discrimination on the ability of many African Americans to achieve material security, which becomes an additional chronic stressor.

## STRESS APPRAISAL, COPING, AND HYPERTENSION

Stress exposure is not a necessary or sufficient condition in predicting increases in resting blood pressure, but rather the stressor must be appraised as chronically stressful in order to affect long-term, stable changes in cardiovascular responses to stress. As Thomas Pickering (1997) suggests, the best predictor of blood pressure increases is the perception that what one is doing is stressful, whether at work or at home. For example, studies of stress and social support have found that perceived stress was correlated with increases in systolic blood pressure, particularly in men. Also, although all stress exposure experiences interact with appraisal processes to influence stress responses, a number of psychological predispositions amplify the experience of being under stress and are implicated in risk for hypertension. These include anger and hostility, especially the tendencies to suppress anger and to react to anger provocation without contemplation, and high trait anxiety and depression.

## BIOBEHAVIORAL STRESS REACTIVITY AND HYPERTENSION

Exposure to stress triggers activation of a number of physiological mechanisms, including the autonomic nervous system (ANS); the hypothalamic-pituitary-adrenal

(HPA) axis; the metabolic, cardiovascular, and immune systems; and the release of stress hormones, all of which mobilize the body for action by increasing heart rate, blood pressure, and respiration, as well as mobilize the immune system to protect against infection. These normal reactions are subsequently inactivated once the stressors are removed or reduced. However, when inactivation is insufficient or incomplete, there is prolonged exposure to stress hormones, which results in an increase in physiological damage and dysfunction.

Central to the stress reactivity hypothesis is the premise that certain individuals evidence heightened cardiovascular reactivity (CVR) in response to stressful situations. Some researchers argue that this reactivity is a marker for the development of hypertension, such that consistently heightened reactivity co-occurs with and indicates dysfunction of one or more blood pressure control mechanisms. On the other hand, others have argued that repeated exaggerated CVR plays a causal role in the development of hypertension, such that repeated exposure to stress in people who are highly responsive to it results in sustained blood pressure elevations, and an individual's blood pressure eventually will be reset at a higher level. Precisely how this resetting might occur is unclear, although structural changes and heightened sympathetic nervous system activity might be potential mediators.

Several research methodologies have evolved to test the stress reactivity hypothesis. In the widely used laboratory stress reactivity paradigm, blood pressure and other cardiovascular measures are recorded before, during, and immediately following exposure to an active (e.g., mental arithmetic) or passive (e.g., cold pressor) stress task. Changes in cardiovascular parameters from baseline to the stressor task and time to recovery are used as indicators of the magnitude of cardiovascular reactivity. An underlying assumption of this paradigm is that responses to standardized laboratory tasks are good indicators of how people typically respond to stresses during their usual day.

To test the latter hypothesis, researchers have developed and refined the methodology for ABPM to capture physiological reactivity to naturalistic stressors. By wearing small, portable blood pressure monitors, periodic blood pressure readings are made during waking activities and sleep over 24 hours, and experience sampling methods are used to record moods, activities, posture, and other potential cofactors with each blood pressure measurement.

Researchers have long debated the evidence supporting the stress reactivity hypothesis and have raised a number of key questions about (1) the reproducibility, (2) lab to life generalizability, (3) predictive power, and (4) discriminatory power of individual differences in CVR.

### Reproducibility

If reactivity to stress is a trait-like marker or contributor to hypertension, then individuals should show consistent, stable cardiovascular responses to different types of stressors over time and in different settings and conditions. To date, however, the evidence of the reproducibility of blood pressure reactivity over time and in response to different stressors is weak, especially for diastolic blood pressure. Some researchers have obtained strong evidence for stability over time by aggregating reactivity across different stressors, while others have pointed out that the temporal stability of reactivity may be a meaningful individual difference, with some individuals showing consistent responses over time and others showing more variability. Evidence for the stability of reactivity across stressors is also mixed, although researchers have suggested that some groups demonstrate different patterns of reactivity to different types of stressors. For example, African Americans generally evidence a different pattern of cardiovascular stress reactivity than Caucasians to a variety of different laboratory stressors, which suggests that there may be Black-White differences in the primary biobehavioral mechanisms and psychosocial factors that contribute to disease risk in these groups.

### Generalizability

If people's responses to laboratory tasks represent how they respond to real-world stressors, then laboratory measures of CVR should yield similar results to those obtained with ambulatory measures. This correspondence is very difficult to capture because the natural environment, as opposed to highly controlled laboratory situations, contains a number of uncontrolled factors that can influence blood pressure at any given point in time. The evidence for generalizability is mixed, with some studies reporting high associations between laboratory reactivity scores and ambulatory measures and others reporting no associations.

It may be that methodological issues contribute to these inconsistent findings. Since laboratory reactivity

occurs in response to behavioral or psychological stimuli, it should correspond to ambulatory measures recorded during real-life events with similar behavioral or psychological features. However, many studies compare laboratory measures to 24-hour ambulatory measures, during which the amount of stress encountered varies considerably from person to person and within the same person from day to day. This inter- and intraindividual variability reduces the correlations between laboratory and ambulatory measurements. Studies that have partitioned ambulatory measurements into periods of perceived or objective stress (e.g., working hours) have found greater correspondence, as have studies comparing responses to laboratory and equivalent real-world stressors (e.g., giving a speech). Still, it seems reasonable to argue that if stress reactivity is a trait, then measures of field reactivity should reflect a wide array of daily changes and that isolated naturalistic stressors thought to affect blood pressure do not provide an adequate test of this hypothesis.

Although the use of laboratory reactivity tests has not been discredited, most investigators would concede that measuring blood pressure under naturalistic, real-life conditions offers the best test of the stress reactivity hypothesis.

### **Predictive Power**

If stress reactivity marks or contributes to the development of hypertension, then cardiovascular hyperreactors should be more likely to develop essential hypertension than less reactive people. This question has been addressed in several longitudinal studies showing that high systolic blood pressure reactors to physical tasks such as the cold pressor and high diastolic pressure reactors to active psychological tasks such as mental arithmetic are at greater risk for hypertension at follow-up than low reactors.

### **Discriminatory Power**

If stress reactivity marks or contributes to hypertension, then hypertensives and those at risk for hypertension (i.e., those with a family history of the disease) should evidence heightened CVR to stressful events. Indeed, research indicates that borderline hypertensives and children of hypertensives demonstrate greater reactivity to laboratory stressors than normotensives and than children without a family history

of hypertension (Bedi, Varshney, & Babbar, 2000). Some animal research parallels these findings, with studies showing that prehypertensive spontaneously hypertensive rats (SHRs) evidence exaggerated CVR.

Finally, recent studies have identified individual differences in patterns of CVR that may have implications for the development of hypertension. For example, although participants may have similar blood pressure responses to a laboratory stressor, some might show changes mainly in cardiac output while others show changes mainly in vascular resistance.

Recent studies also have begun to focus more attention on patterns of blood pressure recovery following peak response to stressful tasks, with growing evidence that hypertensives and those at risk for this disease typically experience slower cardiovascular recovery following stress exposure than normotensives.

Thus, blood pressure hyperreactivity to stress appears to discriminate people at risk for hypertension and, in some studies, predict later development of essential hypertension. However, inconsistent methodologies have generated mixed evidence for the generalizability of laboratory reactivity to the real world, and there is limited evidence for the reliability of laboratory responses across time and stressors.

## **BEHAVIORAL TREATMENTS OF HYPERTENSION**

Our efforts to identify the contributions of stress in hypertension have been complemented by efforts to develop and test a range of behavioral approaches to the treatment of this disease. Blumenthal, Sherwood, Gullette, Georgiades, and Tweedy (2002) provided a very thoughtful review of this evidence and concluded that there are a number of behavioral approaches to the treatment of essential hypertension that have yielded positive results. These approaches offer several advantages over traditional pharmacotherapy in that they generally have no negative side effects, patients have more control over their use, and they are generally cost-effective. However, there is little justification at this time for using any of these approaches as first-line substitutes for blood pressure control medications, except perhaps as a preventive strategy for those who have high normal blood pressure or are borderline hypertensive.

Several behavioral interventions are considered effective and are frequently prescribed as first-step interventions with borderline and mild hypertensives, including reductions in dietary intake of sodium,

which has been shown to produce the most consistent and strongest correlation with blood pressure reduction; reductions in saturated fats, along with increases in intake of calcium and potassium, and weight loss; reduction or cessation of smoking and alcohol consumption; and increases in physical exercise, especially aerobic exercise of moderate intensity. However, a recent meta-analysis of randomized clinical trials with these interventions suggests that the reported beneficial effects may be overestimated because of failure to control for the confounding effects of concurrent changes in other behaviors and life circumstances (e.g., increase in exercise is often associated with reducing stress and/or the magnitude of response to stress) (Ebrahim & Smith, 1998).

There is also a very large body of published research on stress reduction or relaxation strategies for hypertension. However, because these approaches are quite diverse and are believed to exert their effects through different mechanisms, the evidence of their efficacy is rather mixed. Some of the contradictory findings can be attributed to methodological weaknesses, including inadequately described or standardized procedures; small, poorly characterized samples; weak study designs with inadequate controls and uncontrolled confounds; and problems with the analytic approaches used. Because of these constraints, this entry includes evidence of the efficacy of only two approaches that are clearly distinct and that have been tested using rigorous methodologies: transcendental meditation and biofeedback-assisted relaxation. A number of smaller studies have also reported positive results for other behavioral approaches, including general relaxation, several approaches to meditation, yoga, and progressive muscle relaxation (PMR).

### Transcendental Meditation

One of the few techniques for meditation that has been widely used and systematically studied is transcendental meditation (TM). A recent meta-analysis indicated significantly greater benefits from TM compared to other clinically devised forms of relaxation on a range of cardiovascular disease risk factors, and these benefits appear to increase proportionate to the intensity and length of time meditating (Orme-Johnson & Walton, 1998). In a randomized clinical trial with elderly African American hypertensives, Schneider et al. (1995) compared the efficacy of TM

with PMR and with a lifestyle modification control intervention, and found consistently greater cardiovascular disease benefits for TM at posttest and at 3 month follow-ups than the other two interventions. PMR also yielded positive results, but the effects were more modest and were different in men and women and in patients with high versus low cardiovascular disease risks.

### Biofeedback-Assisted Relaxation

There is also strong evidence in support of the utility of biofeedback-assisted relaxation (BAR) in the treatment of hypertension, with the best results obtained with EMG and thermal biofeedback. These studies generally report clinically meaningful reductions in blood pressure, as well as in muscle tension, urinary cortisol, and anxiety levels, and these effects are maintained in some patients up to 1 year posttreatment. Glasgow, Gaarder, and Engel (1982) reported that the best results are obtained when biofeedback is combined with and precedes relaxation training, and appears to be most effective in mild hypertensives with evidence of autonomic hyperactivity (e.g., cool hands, high heart rates) and no organ damage.

## SUMMARY AND CONCLUSIONS

Available evidence supports the hypothesis that exposure to high chronic stress is associated with enhanced risk for the development of essential hypertension, but mainly in those who are biologically predisposed to hypertension as evidenced by a family history of the disease, inefficient sodium metabolism, and cardiovascular hyperreactivity and slow recovery from exposure to acute stresses. While the debate about the meaningfulness of laboratory stress reactivity in accounting for hypertension risk continues, the most compelling and potentially useful evidence of the stress-hypertension relationship comes from studies using the latest in ABPM methodology, which allows for the measurement of blood pressure responses to naturalistic, real-life stresses. Recent studies also underscore the importance of investigating multiple sources of stress, especially those that might account for group differences in exposure to different types, sources, and amounts of stress.

To date, there is no compelling evidence that stress is an independent causal factor in this or in any other disease, but it appears to be a very important contributor

to hypertension and its sequelae. The evidence is also very strong that the stress-disease relationship is exacerbated by concurrent behavioral risk factors (e.g., obesity, high fat and sodium intake, abuse of alcohol and recreational drugs, and sedentary lifestyle) and psychological factors (e.g., repressive coping style, suppressed anger coping, high trait anxiety, and depression).

Several behavioral approaches have been tested as possible therapeutic adjuncts to pharmacotherapy in the treatment of hypertension, and current evidence indicates that while positive results have been obtained with several of these approaches, the strongest evidence of therapeutic efficacy has been obtained with TM and with BAR, especially for mild hypertensives with evidence of autonomic hyperactivity and no evidence of organ damage secondary to this disease.

## BOGALUSA HEART STUDY

---

### BACKGROUND

In 1972, the long-term investigation into the early natural history of arteriosclerosis, which was to become known as the Bogalusa Heart Study, received its initial funding as a Specialized Center of Research-Arteriosclerosis (SCOR-A) of the National Institutes of Health. The funding was in response to a congressional mandate to investigate the major causes of cardiovascular disease. The Bogalusa Heart Study has expanded into a long-term, uninterrupted study over 30 years and is the only study in the United States of a biracial (Black-White) community focusing on the

development of early cardiovascular risk in children. The major question of the Bogalusa Heart Study was how coronary artery disease and essential hypertension begin in a well-defined geographic and biracial (Black-White) population. The study, therefore, was descriptive and focused on observing a free-living pediatric population in a rural community, comparable to many southern areas of the United States where there is high cardiovascular disease mortality. Over the course of the study, there were seven cross-sectional surveys of school-age children, six longitudinal studies of young adults extending into middle age, and special studies related to lipids and hypertension. The study has resulted in the publication of four books, several monographs, and 700 scientific manuscripts.

The major questions that have guided the study are (1) What are the distribution and prevalence of cardiovascular risk factors in children? What methods can be used to obtain reliable risk factor information on children? How are risk factors defined in childhood? What levels of risk factor variables in children are above the norm and relate to underlying or predict future cardiovascular disease? (2) What are the inter-relationships of risk factors? Are the relationships similar to those in adults? (3) What are the secular trends in risk factors in children? How do risk factors change over time? (4) What are the determinants of risk factors in children? Do risk factors reflect genetic/environment interactions?

## MAJOR ACCOMPLISHMENTS

The most impressive accomplishments within a 30-year history can be summarized as follows:

- The major risk factors for cardiovascular disease begin in childhood, with documented relationships with autopsy changes in coronary arteries.
- Methods to study cardiovascular risk factors have been developed, and normative values from a large biracial (Black and White) population are available for national comparison.
- Levels of risk factors in children are different than those in adults. Levels change with growth phases, infancy, childhood, adolescence, and young adulthood.
- Environmental factors are significant and influence cardiovascular disease and obesity. The major modifiable factors include diet, exercise, and tobacco use.
- Lifestyles and behaviors that influence cardiovascular risk are learned and begin early in life. Cardiovascular

health education and promotion needs to begin in childhood to encourage adoption of healthy behaviors that can reduce or prevent risk factors in later life.

## BIOBEHAVIORAL STUDIES

Protocols for the Bogalusa biobehavioral studies included the following for each study variable: (1) prevalence, (2) demographic variability, (3) secular trends, (4) associations with cardiovascular risk factors, and (5) comparisons with national studies. Main areas of study were (1) tobacco and alcohol use; (2) diet; (3) physical activity; and (4) psychosocial variables, such as Type A-B behavior, learned helplessness, assertive communication, and anger.

*Tobacco and alcohol use.* Information regarding the smoking behaviors of children and adolescents has been obtained in Bogalusa since 1973 by a self-report questionnaire and has been validated with plasma thiocyanate. Some important findings throughout the study showed that White boys adopt cigarette smoking earlier than the other race/sex groups, the percentage of White girls who smoked increased and surpassed the boys by the late teens, and Black boys and girls had lower prevalence and lagged behind White children in their smoking experience. Smoking attitudes and first use were consistent over time in that parental modeling, and sibling and/or peer influence dominated. Approximately 30% of high school-age students reported regular tobacco use. Smoking was found to associate positively with alcohol use, and for White boys, this clustering was also associated with hostility.

Alcohol use has been obtained from school-age children and adolescents since 1981 by a self-report instrument similar to the smoking questionnaire. The highest percentage of regular drinkers was among White males and the lowest among Black females. Prevalence of regular alcohol consumption among school-age children (e.g., approximately 30% of high school-age students) was generally lower than national rates; however, the reported prevalence is within an age group for which purchasing alcohol is illegal in Louisiana. Young third to sixth graders' attitudes were generally negative regarding drinking alcohol, and most who had experimented had family members who consumed alcohol.

*Dietary intake/eating patterns.* Dietary data have been collected from six cohorts of 10-year-olds and two cohorts of 13-year-olds since 1973. A major finding

was that school-age children eat the typical American adult diet, characterized by high intakes of sodium, refined carbohydrates, animal protein and fat, and low intakes of potassium, complex carbohydrates, and vegetable protein and fat. Secular trends indicated that total fat intake has decreased from 38% to 34% over time. Ongoing dietary monitoring indicated that, as obesity increased, caloric energy intake remained stable but decreased when related to body weight. Over the past 20 to 30 years, school-age children on average are 5 kilograms heavier without increase in stature.

*Psychosocial factors.* The Bogalusa Heart Study was just getting started shortly after the time that the Type A-B "behavior pattern" was identified as an independent risk factor for cardiovascular disease. The Hunter-Wolf Type A Behavior Scale was developed for use with children and adolescents and was tested through direct observation for validity and reliability. This scale was used in the cross-sectional surveys and findings indicated that global Type A score increased with age and were consistently higher for White males than the other race/sex groups. Consistent associations with cardiovascular risk factors in the school-age group were not observed. Eventually, Type A declined in importance when it was found in longitudinal follow-ups of major cardiovascular adult studies that Type A no longer appeared as a risk factor for cardiovascular mortality. Hostility and "eagery" (a combination of *eagerness* and *energy*, a term coined by the developer of the Type A survey used in the Bogalusa Heart Study), however, were found to be part of the adverse components of the Type A complex. Anger/hostility, examined further, indicated that overt anger was higher in White children and repressed anger was higher in Black children.

Learned helplessness, a cognitive and behavioral response set to repeated failure, was studied in the beginning of the 1990s. It was found that learned helplessness was significantly associated with all indices of obesity for White females and with waist/hip ratio for Black females at the high school-age level. Based on identifying cardiovascular disease as present in childhood by autopsy findings and that risk factors strongly relate to underlying atherosclerotic and hypertensive lesions, the major modifiable lifestyles of poor nutrition, inactivity, and smoking need to be addressed early in life. To begin prevention as a population, or public health, approach an extensive and coordinated health education program

(Health Ahead/Heart Smart) was developed for K-6 grade school children.

## BULIMIA NERVOSA: TREATMENT

---

Although bulimia nervosa (BN) was first described in the late 1970s, considerable research has been devoted to developing treatment for this disorder. At this point, several strategies with varying degrees of effectiveness are available. They include several different types of psychotherapy, as well as antidepressant medication.

### PSYCHOTHERAPY

A number of different psychotherapeutic approaches to BN have been investigated. Each has its own conceptualization of the disorder and distinct procedures for treating the problem. They include cognitive-behavioral therapy, interpersonal psychotherapy, and dialectical behavior therapy.

#### Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is based on the assumption that how we interpret events affects how we respond behaviorally and emotionally. CBT has been applied to a number of psychiatric disorders with varying degrees of success. The procedures that comprise CBT for bulimia are based on two major assumptions. The first is that the symptoms of bulimia are strongly related to attitudes toward weight and shape. Specifically, while pressures to be thin are pervasive in Western culture, those with BN are thought to be particularly vulnerable to such pressures and to gauge their own self-worth overly, if not exclusively, in terms of weight and shape. Thus, they strongly fear becoming obese. Second, it is assumed that such fears bring about unrealistic and rigid self-imposed guidelines regarding food consumption. The eating patterns of bulimics are characterized by dietary restriction, which may include attempts to strictly avoid certain foods judged to put the individual at risk for weight gain as well as habitually skipping meals. Dietary restriction, in turn, leads to binge eating both because the individual often becomes overly hungry and also may react adversely to consuming foods that are considered forbidden. One example of the latter is eating a small amount of such food, becoming upset or disinhibited by breaking one's self-imposed rule, and eating a very large quantity of that food. The individual engages in purging behavior such as self-induced vomiting or laxative abuse to "undo" the effects of a binge and avoid

weight gain. The eating pattern of the bulimic has often been referred to as consistent with a "binge-starve cycle."

CBT for bulimia is generally carried out over 18 to 20 sessions. Education about eating and weight is an important part of treatment and includes information about the ineffectiveness of laxative abuse in weight control, the negative physical consequences of self-induced vomiting, and the ways that dieting can bring about bulimic symptoms. A second key feature of treatment is self-monitoring, which involves keeping a detailed record of all eating episodes. The daily record typically includes the following information regarding food consumption: when and where eating took place, degree of hunger, type and quantity of food eaten, degree of fullness after eating, whether the person labeled the episode a binge, and whether purging took place. Self-monitoring provides important information regarding the pattern of eating including meals that are typically skipped, foods that are consumed as well as avoided, and other "triggers" for bingeing and purging episodes. A third component of treatment is changing the pattern of eating in such a way that the person learns to eat three meals daily and one or two snacks and begins to consume modest amounts of food previously considered forbidden. This takes place gradually but consistently throughout treatment. Fourth, the treatment is designed to assist the patient to critically examine and change attitudes toward eating, weight, and shape. Examples of targets for cognitive change may include catastrophic thoughts about minor fluctuations in weight, beliefs that sweets or foods rich in carbohydrates should never be eaten, and beliefs that eating three meals a day will invariably lead to substantial weight gain.

CBT for BN is considered the most effective available treatment. It is associated with reductions in bingeing and purging behavior of 80% to 90%. Approximately 40% to 50% of those receiving CBT remit, that is, stop bingeing and purging altogether. In general, studies that have tracked progress once active treatment has ended have reported that gains made with CBT are maintained reasonably well. In addition, CBT is associated with reductions in dietary restraint, improved attitudes toward weight and shape, and improvements in mood and self-esteem. Moreover, despite fears about the consequences of eating regularly, the available evidence suggests that the majority of those treated do not gain weight. This is probably because as regular meals come to supplant binges, the

overall number of calories consumed daily decreases or remains largely unchanged.

### Interpersonal Psychotherapy

Like CBT, interpersonal psychotherapy (IPT) has been applied to other psychiatric disorders, particularly major depression. The rationale for IPT in BN is that bulimics typically present with a number of interpersonal problems that may precipitate mood fluctuations and lead to binge/purge behavior. As opposed to CBT, which focuses more directly on the specific eating-related symptoms of BN, IPT focuses much less on eating difficulties and typically targets one among a group of four possible interpersonal problem areas: role transition, interpersonal role disputes, grief, and interpersonal skills deficits. In addition, IPT is a less directive form of psychotherapy than CBT.

As applied to bulimia, IPT is generally carried out over 18-20 sessions with three distinct phases. The initial phase involves review of the individual's past and current relationships as well as a life chronology that identifies relationships among significant life events, mood and self-esteem, interpersonal relationships, and changes in weight. The first phase of treatment culminates in a "life chart" that illustrates the links between particular life experiences and symptoms of bulimia. One of the four problem areas noted above is usually identified as the chief focus of treatment and targeted for change.

The middle phase of treatment is devoted to attempting to resolve issues in the identified problem area. For example, if grief is the area identified, steps would be taken to identify links between the death of a loved one and the bulimic symptoms, facilitate the mourning process, and assist the patient to reestablish new relationships. If a primary problem involved a role transition (e.g., moving away from home to attend college), the steps might include elaborating the meanings associated with the transition, identifying perceived advantages and disadvantages as well as obstacles to making the transition, and practicing skills necessary complete the transition and establish appropriate social supports.

The final treatment phase involves summarizing and solidifying changes that have been made. In addition, a review is undertaken of specific changes in eating behaviors and how these relate to changes in interpersonal patterns.

IPT has been compared to CBT in several trials. In general, the results suggest that IPT is associated with results that are somewhat more modest. Over the short term, compared with CBT, IPT is associated with smaller reductions in binge eating and purging as well as lower rates of abstinence. However, over longer periods of time, IPT appears to "catch up," suggesting that while it may be reasonably effective, compared with CBT a longer period of time is required to bring about maximum improvement.

### Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) was originally developed for those with borderline personality disorder, who often cope with negative emotional experiences with self-mutilation or other self-destructive behavior. DBT specifically aims to facilitate improved affect regulation and tolerance for emotional distress. The rationale for employing DBT for BN is that negative mood frequently precipitates binge/purge episodes and that the latter may serve as a way of escaping from unwelcome emotions. DBT aims to decrease symptoms of bulimia by increasing the individual's ability to modulate strong emotions.

The skills taught in DBT include "mindfulness" or nonjudgmental awareness. This involves decreasing judgment of one's own emotional responses. Other facets of treatment include skills in reducing emotional vulnerability by changing behavior patterns associated with negative emotion. One way of accomplishing the latter involves the use of behavioral chain analysis. With this procedure, problematic behaviors, such as binge/purge episodes, are examined in terms of precipitating events and the detailed sequence of thoughts, sensations, feelings, and behaviors that preceded the episode.

To date, DBT was evaluated in only one trial with bulimics. However, the results were quite promising. The remission rate was close to 30%, and reductions in binge/purge episodes were above 85%. No long-term follow-up data are available at this time.

### ANTIDEPRESSANT MEDICATION

The rationale for the use of antidepressant medications for BN developed from observations that mood disturbances are common among those who have BN. A large number of controlled trials have investigated

the efficacy of a variety of antidepressant medications in reducing the symptoms of BN, including tricyclic antidepressants, monoamine oxidase inhibitors (MAOI), specific serotonin reuptake inhibitors, and others. In general, most of the antidepressant medications tested with bulimics have been found to be significantly superior to placebo. Overall, the reductions in purging are approximately 60% and remissions are approximately 30%.

A number of studies have specifically either compared antidepressants with CBT or investigated whether combining the treatments is more helpful than either alone. Overall, these studies suggest that CBT produces better results than medication alone. There is also evidence that combining the treatments produces modest enhancements in outcome. Little is known about the long-term effectiveness of antidepressant medication.

Interestingly, while antidepressant medications for BN seem to be associated with improvement in mood, there is no relationship between being depressed at the beginning of treatment and improvement in symptoms of BN. That is, whether or not an individual's symptoms of BN reduce with antidepressant medication is unrelated to the level of depression at the beginning of treatment. Thus, why the treatment is helpful remains unclear.

## TREATMENT SETTING

While residential or inpatient treatment is available for those with BN, there is no evidence that it provides benefit over the less expensive outpatient treatments described above. Inpatient treatment is generally appropriate only for those who are at risk for suicide, or develop serious medical problems either as a consequence of bulimia or some other disorder.

## CANCER AND DIET

---

In recent years, there has been an explosion of prospective studies on diet and chronic disease, and this has greatly furthered our understanding of cancer etiology. Much of the hypothesized relation between diet and cancer comes from studies of the variation in cancer rates between countries and the change in both diet and cancer rates when populations migrate from one country to another. Building on international correlation studies and retrospective case-control studies, prospective cohort studies offer the potential to evaluate diet-disease relationships free from recall bias and to correct for measurement error.

Current evidence from these prospective studies suggests that, on a global scale, diet and obesity cause approximately the same proportion of cancers each year as tobacco use does. That is, nearly one third of all cancers (or 3 million to 4 million cases worldwide) are caused by diet and obesity—and could thus be prevented by improvements in nutrition and physical activity. Specifically recommended is a diet rich in plant-based foods and moderate in meat and alcohol. In addition, for cancer prevention and overall health, this diet must be balanced with regular physical activity. Below we summarize the evidence for these recommendations, outlining the specific effects that various foods and nutrients, as well as weight and physical activity, have on cancer risk.

Although diet, weight, and physical activity have been considered in relation to various types of cancer, this review focuses only on associations that are convincing or probable. The weaker possible associations

are not discussed. In order for an association to be considered convincing, there must be consistent epidemiological findings across a large number of well-designed studies, demonstration of a dose-response relationship, a biologically plausible mechanism, and supportive laboratory evidence. Probable associations are those for which there is supportive laboratory or mechanistic evidence, but the epidemiological evidence is inconsistent or not extensive enough to make definitive judgment.

### FOODS

Although scientists can now isolate many of the specific components of foods, it is still important to consider the effect that whole foods have on health. After all, people buy, prepare, and eat whole foods rather than specific nutrients. In addition, despite advances in technology and study methodology, researchers cannot always tell which component of a food is responsible for which risk or benefit. In the instances that they can, it might be unclear whether the component is working alone (and so could be taken as a supplement) or whether it functions only in concert with other ingredients in the food. For example, at one point, vegetables were thought to lower the risk of lung cancer, and beta-carotene was thought to be the main ingredient offering protection. However, when researchers gave beta-carotene supplements to smokers, they found no reduction in the risk of lung cancer. In fact, they found a somewhat elevated risk. This may be because researchers focused on the wrong component of vegetables—or because beta-carotene does not have the same effect on lung cells

when it is taken alone versus with other vitamins and minerals in vegetables. It may also be that a combination of carotenoids is more important than beta-carotene alone. Regardless, this example points to the importance of understanding how both specific nutrients and whole foods affect health.

### Fruits and Vegetables

For many years, the most abundant evidence for an effect of diet on cancer risk was related to fruits and vegetables, with higher intake proposed to lower risk. However, the large majority of this evidence arose from case-control studies, and prospective data have been far less consistent. In fact, prospective cohort studies are supporting fewer and fewer associations between overall fruit and vegetable intake and the risk of cancer. Although once considered convincing, the evidence is now considered only probable for associations between a high intake of fruits and vegetables and cancers of the pancreas, bladder, mouth, pharynx, larynx, esophagus, and stomach.

Although total fruit and vegetable intake may not provide the blanket benefit it was once thought to, researchers are now considering the possibility that specific types of fruits and vegetables might offer protection against certain types of cancer. For example, tomatoes have been proposed to lower the risk of prostate cancer, and green leafy vegetables have been studied in relation to both stomach and lung cancer. However, these relationships—and the many others that are currently being investigated—need further study before they can be considered convincing or even probable.

Numerous mechanisms have been proposed to explain the potential benefits of fruit and vegetables in terms of cancer risk. Most have focused on the effects of specific agents in these foods, such as carotenoids, selenium, folic acid, fiber, and vitamins C and E. However, Steinmetz and Potter (1991) have suggested that fruits and vegetables contain an “anti-carcinogenic cocktail” of substances, including both recognized nutrients and nonnutritive constituents. Together, these substances inhibit the formation of carcinogens, act as substrates for the endogenous production of anticarcinogens, reduce the capacity of transformed cells to proliferate, and act as antioxidants.

Despite the diminishing evidence with respect to cancer, fruits and vegetables are still recommended as part of an overall healthy diet. These foods lower the

risk of hypertension, coronary heart disease, and ischemic stroke, in addition to containing vitamins and minerals that protect against a host of other conditions.

### Red Meat

There is evidence that a high intake of red meat probably increases the risk of colorectal cancer among both men and women. Although not entirely consistent, numerous studies of both cohort and case-control design have reported a positive association between red meat and colon cancer. For most studies showing an association, the increase in risk was about twofold for those consuming the most red meat compared to those consuming the least.

Several mechanisms have been proposed to explain this. First, the specific fatty acid content of red meat may be particularly harmful. However, the fatty acids in beef are not unique and overlap substantially with dairy fat, which is not related to colon cancer. Second, fat from red meat may be less readily digested or absorbed in the small intestine than fat from other sources; therefore, more of it may reach the large bowel. Third, initiators or promoters may be formed when red meat is cooked, particularly at high temperatures. Finally, frequent consumption of red meat may increase concentrations of fecal iron, which could influence the risk of colon cancer via the generation of hydroxyl radicals.

### Alcohol

Because alcohol use tends to be associated with cigarette use and other high-risk behaviors, its independent effects on cancer have long been questioned. However, in 1988, on the basis of abundant epidemiological evidence, the International Agency for Research on Cancer concluded that alcohol is in fact a carcinogen and an independent risk factor for cancers of the upper aerodigestive tract and liver. Since that report, a large body of evidence has confirmed that alcohol use also increases the risk of breast cancer and probably colon and pancreatic cancer.

Although numerous studies have compared the individual effects of beer, wine, and liquor, the type of alcohol consumed does not appear to influence cancer risk as much as the amount. For cancers of the upper aerodigestive tract, breast, colon, and rectum, there is a dose-response relationship, such that even low or

moderate intake (of any type of alcohol) increases risk slightly. For liver cancer, the most important factor is heavy and persistent use, such as that defined by alcoholism.

In contrast to its harmful effects on cancer and other conditions, alcohol has proven benefits in terms of cardiovascular health. Moderate alcohol consumption reduces the risk of death from coronary heart disease by 20% to 40%. Because cardiovascular disease is the leading cause of death in middle age and beyond, a reduction in cardiovascular mortality risk will translate, for many populations, into a reduction in total mortality risk. Clearly, this benefit of alcohol must be balanced with its many risks.

## Nutrients

In addition to whole foods, there is growing evidence that specific macronutrients and micronutrients might also affect cancer risk. Macronutrients are the major nutrients (such as fat, carbohydrates, fiber, and protein) that the body needs in large quantities to function properly. Although there is evidence suggesting possible relationships between a variety of macronutrients and site-specific cancers, more solid evidence exists for only one association: animal fat and prostate cancer. Even this is considered only probable and is still being investigated.

For micronutrients, some stronger links exist, with the most established being between folate and colorectal cancer. A number of studies have found that as folate intake increases, the risk of colorectal cancer (as well as polyps) decreases. The Nurses' Health Study found that a high intake of folate-rich foods, such as fruits and vegetables, was sufficient to lower risk, but that supplementation with a multivitamin that contained folate offered even greater reductions. The underlying biologic role of folate and its interaction with the MTHFR gene add support to the causal relation between low folate and colon cancer. In addition, there is evidence that the risk of colorectal cancer may also be lowered with calcium supplementation.

The association of vitamin A and carotenoids with cancer risk has also been studied extensively, with the strongest evidence supporting a probable link with breast and lung cancers. Currently, however, it seems there is only a small reduction in the risk of breast cancer associated with a high intake of carotenoids. And while a number of observational studies support an association between high carotenoid intake and

lower risk of lung cancer, randomized trials of the carotenoid beta-carotene intake found either no effect or an increased risk of lung cancer.

## PHYSICAL ACTIVITY AND WEIGHT

For overall health, as well as cancer prevention, energy intake (as measured by diet) must be balanced by energy expenditure (as measured by physical activity). Clearly, one's weight is a reflection of that balance: obesity results from a sustained positive energy imbalance and is often a consequence of lifelong inactivity. Although physical activity and weight are related to diet, they are also independently related to cancer risk.

### Physical Activity

High levels of physical activity reduce the risk of colon cancer and breast cancer. Among both men and women, high levels of activity may reduce colon cancer risk by as much as 50%. Although studies have not consistently used a standard measure of physical activity or defined exactly what constitutes a "high" level of activity, an inverse dose-response relationship between activity and colon cancer has been consistently observed across various study designs and populations. Several mechanisms have been proposed to explain this. First, physical activity may speed the passage of stool through the gastrointestinal tract, thereby minimizing contact between the bowel wall and any potential carcinogens in the stool. Second, physical activity may reduce circulating levels of insulin, which is a growth factor for epithelial cells in the colon. Finally, physical activity may alter prostaglandin levels, improve immune function, and modify bile acid metabolism.

Although not entirely consistent, the majority of studies also suggest that physical activity may modestly lower the risk of breast cancer. A woman's risk of breast cancer depends largely on the amount of estrogen circulating in her body, and physical activity can influence this. Long-term activity can reduce levels of circulating ovarian hormones in premenopausal women and can reduce the amount of adipose tissue in postmenopausal women. Adipose tissue is the primary source of estrogen after the ovaries stop producing hormones.

Physical activity in early childhood may also affect breast cancer risk. By interacting with the adrenaline system to reduce levels of circulating estrogens, physical

activity may result in delayed menarche. In addition, young girls who are physically active have less adipose tissue, and this may also delay menarche. Early age at menarche (< 12) is an established risk factor for breast cancer.

## Weight

Epidemiological studies that have assessed the effect of body weight on cancer risk have taken into account a variety of factors related to weight, including dietary intake, physical activity, health status, and hormonal factors. From these studies, there is conclusive evidence that body weight influences the risk of cancers of the endometrium, breast, colon, kidney, and esophagus. Current evidence also suggests a probable relationship between obesity and prostate cancer.

The evidence is most convincing for endometrial cancer, where a positive dose-response relationship has been observed consistently. Risk appears to be particularly elevated among older women who are overweight and among those who experience weight gain during adulthood. Overall, obese women appear to be about twice as likely to develop endometrial cancer as lean women. Similar trends have been observed for breast cancer and are most likely due to the effect of body weight on levels of endogenous estrogens.

In terms of colon cancer, obesity appears to influence the development of adenomatous polyps and the progression of polyps to malignancy. Both men and women with excess body weight are at increased risk of polyps and colorectal cancer, with two large cohort studies suggesting a 50% increase in risk among those who are obese. Although the underlying mechanism for this is not yet known, there is strong evidence supporting a relationship between excess weight and glycemic control. Obesity is related to increased insulin resistance and hyperinsulinemia, which in turn are related to the proliferation of colon cells in laboratory studies. Further evidence supporting this mechanism comes from studies of the insulin-like growth factor (IGF) pathway, which have demonstrated that IGF is directly related to colon cancer risk.

Kidney cancer is another disease influenced by obesity in both men and women. Virtually every study that has examined this relation has observed a positive association, though it is usually stronger among women than men. Although this gender difference has suggested to some that the underlying mechanism may be related to hormonal changes, there is little

epidemiological evidence linking hormone-associated variables with kidney cancer.

Esophageal cancer has also been linked convincingly to body weight. Obesity is a known cause of gastroesophageal reflux, a risk factor for esophageal adenocarcinoma. In a population-based case control study from Sweden, a strong direct relation was observed, with a relative risk of 16 for obese adults compared to lean adults. Other studies have also observed this relation with adenocarcinoma, though the magnitude of effect has been weaker.

In addition to the convincing links described between weight and cancer, there is also evidence of a probable relationship between obesity and prostate cancer mortality. Several studies have suggested that obesity may predispose to more aggressive tumors or, alternatively, that it may foster proliferation of prostate cancer after it has developed. Possible mechanisms involve a range of hormones, including the IGF pathway, insulin itself, and, potentially, androgens.

## CONCLUSION

Diet, combined with obesity and lack of physical activity, contributes substantially to the risk of cancer in the population. Though convincing evidence is often lacking on the link between various components of diet and cancer, enough evidence exists to make some overall recommendations. A prudent, risk-reducing diet—especially when other chronic diseases are considered—should minimize red meat consumption and emphasize plant-based foods, such as fruits, vegetables, and whole grains. And there is growing evidence that taking a multivitamin containing folate may substantially lower cancer risk. Increasing physical activity levels should also have significant benefit, reducing cancer risk through improved glucose metabolism as well as preventing weight gain and its associated cancer risk. As research advances and scientists identify additional components of diet that are related to cancer, new strategies will likely be developed to further reduce the burden of cancer in society.

## CANCER AND PHYSICAL ACTIVITY

---

Physical activity holds relevance across the cancer control continuum, from prevention to survivorship. Physical activity has been defined as bodily movement produced by skeletal muscle contractions that increase the amount of energy expended over resting metabolic rate (U.S. Department of Health and Human Services, 1996). Current research evidence suggests that physical activity may not only prevent certain cancers from occurring but may also help individuals manage some of the difficulties related to cancer treatments (e.g., physical side effects, poorer quality of life) or help individuals improve their health following treatment for cancer.

Observational studies (i.e., cohort and case-control designs) support the view that regular physical activity can protect against susceptibility to cancers at specific sites, with the strongest evidence for colon and breast cancer (International Agency for Research on Cancer [IARC], 2002; McTiernan, Ulrich, Slate, & Potter, 1998). Cancer *site* refers to the particular tissue or organ in the body where cancer develops. Some of the evidence to support the link between physical activity and cancer risk is drawn from population-based studies conducted in the United States, Europe, and Asia that assess physical activity and track cancer incidence in thousands of individuals over time, or from large-scale case-control studies conducted in the United States, Europe, Asia, and Australia (IARC, 2002; Thune & Furberg, 2001). For example, the Harvard Alumni Study followed over 17,000 men for up to 24 years and found a link between physical activity and cancer risk (Lee, Paffenbarger, & Hsieh, 1991). However, definitive conclusions concerning

the influence of regular physical activity on cancer require studies that are able to more clearly establish a causal relationship between physical activity and cancer. Intervention studies on physical activity and primary prevention of cancer have not been conducted (Thune & Furberg, 2001), and the intervention studies on physical activity following cancer diagnosis are preliminary. The following highlights the current evidence linking physical activity to cancer at various sites, proposed mechanisms for these links, and select methodological challenges that exist when examining the association between physical activity and cancer. (For a more detailed discussion of specific studies, see IARC, 2002.)

## OVERALL CANCER RISK

Overall cancer risk refers to the generalized risk of developing any type of cancer, without specificity in terms of the cancer site (i.e., particular tissue or organs in the body). The evidence for the influence of leisure time (also referred to as recreational) and occupational physical activity on overall cancer incidence or mortality is inconsistent. Some studies find that physical activity is associated with decreased cancer risk, while other studies find no association and a few find a positive association, that is, an increased risk associated with higher levels of physical activity. One explanation for these inconsistent findings is that combining cancers at various sites into an overall index can mask significant relationships between physical activity and cancer at specific sites. That is, when an overall index of cancer occurrence is used as the outcome, strong or consistent effects of physical activity on cancer on a particular site (e.g., colon) may be hidden because the absent, weak, or inconsistent effects of physical activity on cancer at other sites may cancel them out. Because of this potential problem, attention has shifted to the examination of physical activity effects on site-specific cancer risk, rather than overall cancer risk.

In general, the beneficial effects of physical activity on overall cancer incidence or mortality, when observed, tend to be stronger in men than women. However, these observed gender differences may be due to methodological issues rather than a reflection of true differences in the effects of physical activity between men and women. In support of this assertion, relatively consistent associations have been reported between regular physical activity and lower breast

cancer rates (see below). Gender comparisons may be complicated by male-female differences in the overall levels of physical activity, as research has generally found that men tend to be more active than women.

Several physiological factors have been proposed to explain how physical activity can reduce overall cancer risk and/or susceptibility to cancers at various sites. These mechanisms include physical activity-related modifications in nonspecific immune functioning (e.g., increased lymphocytes, natural killer cells, and macrophages), weight maintenance (e.g., reduced body mass index, improved body fat distribution), metabolic regulation (e.g., increased insulin sensitivity, lower plasma triacylglycerol concentrations), and endogenous hormones. For the most part, the nature of the relationships between physiological mechanisms, physical activity, and cancer has only begun to be elucidated.

### Cancers of the Colon and Rectum

Results from studies that have examined physical activity in relation to the risk of colon and rectal cancers combined (usually referred to as colorectal cancer) have been mixed. This may be due, in large part, to differential effects of physical activity on colon and rectal cancers among studies that do not differentiate the two cancer sites. Higher levels of physical activity (measured as leisure time, occupational, or overall activity) have consistently been associated with lower colon cancer incidence in both cohort and case-control studies, even after considering factors that may confound the relationship (e.g., age, gender, diet, smoking behavior, family history, body mass index). It has been estimated that increased physical activity is linked to a 40% reduction in colon cancer risk and that 13% to 14% of colon cancer cases can be attributed to physical inactivity (IARC, 2002). In contrast to colon cancer, the occurrence of rectal cancer tends to be weakly related or unrelated to physical activity.

A leading mechanism proposed to explain how increased physical activity protects against colon cancer (and the weak association of physical activity with rectal cancer) is decreased intestinal or bowel transit time and subsequent reduced exposure of the colon to potential cancer-causing agents in stool. In contrast, rectal exposure to carcinogens in stool is less pronounced and would be less affected by exercise-related decreases in bowel transit time. Exercise-induced changes in other physiologic factors (e.g.,

prostaglandin, insulin, or antioxidant levels) have also been implicated as protective mechanisms responsible for decreased colon cancer risk.

### Breast Cancer

The weight of evidence, albeit mixed, suggests that regular physical activity (measured as leisure time, occupational, or overall activity) may protect against breast cancer incidence. The protective effects of physical activity on breast cancer risk do not diminish even after considering the influence of potential confounding factors (e.g., age, body mass index, diet). Graded dose-response relationships between physical activity and breast cancer also have been documented, with higher levels of physical activity linked to lower breast cancer risk among both premenopausal and postmenopausal women. Increased physical activity has been associated with a 20% to 40% reduction in breast cancer risk on average, and approximately 11% of breast cancer cases are attributable to physical inactivity among postmenopausal women (IARC, 2002).

Physical activity may influence breast cancer incidence through a number of mechanisms. Possible hormone-related explanations for the benefits of increased or regular physical activity on breast cancer risk among premenopausal women include irregular or reduced number of menstrual cycles and delay of age at menarche. These exercise-related changes are thought to decrease overall or lifetime exposure to endogenous hormones (i.e., estrogen and progesterone), a previously established breast cancer risk factor. Among postmenopausal women, increased or regular physical activity may reduce exposure to estrogen concentration by lowering body fat, a main source of estrogen following menopause. Modifications in insulin levels, energy/dietary intake, and immune functioning have also been implicated as important mechanisms in the causal pathway between regular physical activity and reduced breast cancer risk.

### Prostate Cancer

No consistent pattern has been documented in the various observational studies examining the relationship between physical activity and prostate cancer incidence. While endogenous hormone levels (e.g., testosterone) have been proposed as a possible mechanism that may link physical activity and prostate cancer, the currently equivocal findings on the relationship

between physical activity and prostate cancer preclude the ability to consider mechanisms with any degree of confidence.

### Other Types of Cancer

The effects of physical activity on cancers in other sites (e.g., cancer of the lungs, pancreas, testis, bladder, skin [melanoma], lymphatic system [lymphoma], kidneys, brain, ovaries, endometrium, stomach) remain to be determined, due primarily to limited available data and discrepant findings from existing studies. Some preliminary studies indicate that regular physical activity is associated with lower risks of lung and endometrial cancers. However, physical activity may increase the risk of cancer in other parts of the body, such as melanoma (due to increased exposure of the skin to the sun) and testicular cancer (among bicyclists and horseback riders due to site-specific trauma or heat). Still, insufficient data currently exist to produce firm conclusions on the effects of physical activity on cancers specific to these other organs or tissues.

### PHYSICAL ACTIVITY AND CANCER FOLLOWING DIAGNOSIS

Limited data exist on the effects of physical activity following cancer diagnosis. Anticancer treatments (e.g., chemotherapy, radiation therapy) can compromise immune function, produce significant side effects (e.g., fatigue, nausea, anemia), and reduce quality of life. Physical activity may offset these adverse treatment effects. Existing data have provided initial support that regular or increased physical activity can enhance health among cancer patients and survivors by reducing treatment-related side effects (e.g., fatigue, nausea, diarrhea), decreasing pain, bolstering immune function, improving fitness (e.g., strength, flexibility, functional capacity), reducing sleep difficulties, decreasing depression, reducing anxiety, and improving overall quality of life. However, further research is required to verify the robustness of these preliminary findings. Whether physical activity levels influence cancer mortality or recurrence among individuals who have already received treatment for cancer also remains uncertain.

### SELECTED METHODOLOGICAL ISSUES

Several methodological issues must be considered when determining whether physical activity positively

or negatively influences cancer, and distinct methodological issues confront physical activity researchers when examining cancer prevention versus cancer treatment/survivorship. Although not exhaustive, the issues briefly discussed here represent some of the major methodological difficulties facing the physical activity and cancer field.

Measurement of physical activity represents a major methodological challenge in cancer prevention studies. Unreliable or less accurate physical activity assessments can hinder the ability to detect significant relationships between physical activity and cancer at various sites. Cancer prevention studies have typically not employed objective or standardized measures of physical activity, but have instead primarily relied on brief, self-reported assessments of occupational, leisure time/recreational, lifetime, or daily activities. In addition, household activities have typically not been assessed in prior cancer prevention research, creating a possible underestimate of overall activity.

Furthermore, the time course over which physical activity provides protection against cancer can be difficult to assess and determine. The development of cancer is typically chronic in nature, and ascertaining the time period(s) when physical activity can curtail this development needs further elucidation. Assessments of physical activity at only one point in the life span of an individual may be insufficient in gaining an understanding of the role of physical activity in cancer prevention. As noted earlier, aggregation of data on cancers at various sites into a single index can result in misleading conclusions by masking the protective effects of physical activity on cancer at specific sites. The paucity of trials of physical activity and cancer prevention also strongly limits the ability to make conclusions about the causal relationships between physical activity and cancer. Much of the prior research is based on observational designs, which cannot insure against bias or confounding factors to the same degree as experimental or randomized clinical trial designs. Consequently, it is possible that factors other than physical activity may be responsible for the reduction in cancer risk noted in prior observational research. The use of cancer biomarkers and intermediate end points (e.g., colon polyps, breast density, serum sex hormones) within clinical trials may help to more conclusively establish causal pathways between physical activity and cancer.

In contrast to studies of cancer prevention, evaluations of the influences of physical activity following

cancer diagnosis have been more likely to involve more precise measurement of activity (e.g., scheduled exercise sessions), employ experimental designs (e.g., intervention vs. control group comparisons), and evaluate the progression of cancer development. However, the samples of cancer patients and survivors of prior studies tend to be small and may not be representative of other individuals who have been diagnosed with cancer (i.e., convenience samples have largely been utilized). In addition, physical activity interventions are sometimes incorporated within a broader treatment program, making it more difficult to determine the specific contributions of physical activity to cancer-related outcomes. The relatively short duration of most physical activity interventions (generally less than 30 weeks) further limits the ability to determine whether and when physical activity influences health following cancer diagnosis.

## RECOMMENDATIONS TO THE PUBLIC

The International Agency for Research on Cancer/World Health Organization (IARC, 2002) recommends that individuals should engage in at least 30 to 60 minutes of moderate-intensity physical activity (e.g., brisk walking) on most days of the week. Sixty minutes of moderate-intensity physical activity per day may be necessary for healthy weight maintenance, depending on dietary intake patterns, and more vigorous-intensity physical activity may confer additional cancer prevention benefits.

## SUMMARY

On the whole, the current literature suggests that regular or habitual physical activity is associated with reduced cancer risk, particularly with respect to colon and breast cancers. Whether physical activity is related to cancers at other sites remains unclear due to limited research and discrepant findings from existing studies. As future studies endeavor to address some of the methodological challenges noted in the current literature, the strength of the relationships between different patterns of physical activity and cancer prevention, as well as survivorship and quality of life following cancer diagnosis, should become increasingly clear.

## CANCER PREVENTION

---

Much of human cancer, perhaps half, could be prevented if actions were taken to modify or eliminate human behaviors and environmental factors known to cause cancer. In a landmark 1981 paper, which has stood the test of time, Doll and Peto estimated that the proportion of cancer due to tobacco use was as much as 30%, to dietary factors approximately 35%, to infection 10%, to reproductive and sexual behavior 7%, to occupational exposures 4%, to alcohol 3%, to sunlight 3%, and to pollution, food additives, industrial

products, medicines, and unknown factors the remaining 8%. In 1993, McGinnis and Foege, taking more of a public health perspective, examined the “actual” causes of all deaths in the United States and estimated that over half could be primarily attributed to tobacco and alcohol use, dietary factors, and lack of physical activity, with some contribution from microbial and toxic agents, sexual behavior, illicit drugs, firearms, and motor vehicle accidents. Reflection on the dramatic changes in cancer incidence and mortality over this century also supports the idea that a substantial amount of cancer can be prevented. In the United States, we know with some certainty that mortality from cancer was approximately 80 per 100,000 a hundred years ago, at the beginning of the 20th century. Since then, the death rate from cancer rose steadily to 135 per 100,000 in 1990 but, in a historic reversal, decreased over the decade of the 1990s. Such dramatic short-term changes could not have been due to any alteration in the basic genetic or physiologic makeup of human beings and are unlikely due to changes in medical care. Rather, they must be due to changes in external factors related to human behaviors and the environment (e.g., tobacco use). Additional evidence comes from tracking cancer rates among migrant populations, like the Japanese moving to the United States, where over just a few generations migrants have taken on the cancer rates of their new host countries, while people of the same genetic makeup who stayed home have maintained the rates of the homeland. This is likely due to exposures to new environmental conditions rather than to the differential migration of persons with an increased susceptibility to cancer.

Taking full advantage of what is already known about the causes of cancer can help maintain and accelerate the current downward trend in cancer mortality. First, it is useful to establish what individuals can do to prevent cancer. A personal approach might start with a thorough understanding of one’s family history, which is a combination of inherited genetic susceptibility, lifestyle, and environmental factors. Mutations in genes such as BRCA1 confer about a 70% chance of developing breast cancer sometime in a woman’s life, but because these and other more powerful (highly penetrant) genes are not common, perhaps no more than 5% to 10% of all cancers can be attributed to them. Nevertheless, when a family history of cancer is present, it can give us an idea of which types of cancers we might be susceptible to

ourselves. If, for example, these are cancers known to be due to tobacco, like lung or bladder cancer, it behooves us to make extra efforts to avoid tobacco.

Preventive options for persons with documented inherited genetic susceptibility to cancer from genetic testing are currently limited and involve hard choices. For women with BRCA1 or 2, for example, options include beginning mammography screening at an earlier age and having it more frequently than normally recommended, the use of tamoxifen, and prophylactic mastectomy or oophorectomy. Each of these options is known to confer substantial protection, but each has potential downsides or is unacceptable to some women.

More common (greater than 1% of the population) but weaker (less penetrant) genes are likely to play a larger role in cancer susceptibility through interactions with other genes and the environment. This is an area of active investigation, and no options for incorporating this information into preventive strategies are yet available.

Knowledge of one’s family history of cancer or of specific genetic susceptibility, although potentially useful, should not detract from following many well-established cancer prevention practices that apply to everyone. By far the most important action is to avoid tobacco use or stop it, once begun. Tobacco use should not be considered just another factor in a menu of cancer-causing agents to be avoided. It is *the* factor most responsible for the rise (and fall) of cancer-related deaths over the last century and is currently estimated to account for around a third of all cancer mortality. Individuals usually become addicted to tobacco in adolescence, and we now know that even occasional experimentation with tobacco in the young is sufficient to lead to addiction. The earlier people start smoking, the more likely they are to become addicted long-term users. Thus, a large part of prevention, beyond not starting at all, is to find ways to avoid even experimenting with tobacco as long as possible. For addicted smokers, many cessation strategies are available. For example, nicotine replacement (e.g., patch or gum) can increase the chances of quitting by twofold and is more effective when accompanied by counseling.

Tobacco use is, however, not just an individual problem, but a societal challenge, and some of the most effective interventions are those that involve legislation and government policies. Such actions may include increasing the price through taxation, decreasing

the availability of tobacco products by eliminating vending machines or requiring age-identification for purchase, or restricting advertising of tobacco products. They may also take the form of clean indoor air laws, which are based on evidence that secondary exposure to tobacco smoke can also contribute to cancer.

Evidence of the role of diet in cancer is not as strong as for tobacco, but for those who do not use tobacco (three quarters of adults in the United States), changes in food intake are probably the major personal strategy that can be followed to reduce cancer risk. Studies have consistently shown that diets that routinely include fresh fruits and vegetables are protective for several cancers, including those of the pharynx, larynx, lung, esophagus, stomach, and cervix. In addition, vegetable consumption, but not fruits, may reduce the risk of colon and rectal cancer. Selection of whole grain products such as whole wheat bread or brown rice over refined grain foods and foods high in refined sugars may also be important. Our understanding of the possible contribution of animal protein and fats as causes of cancer is less clear, but the evidence that red meats and processed meats contribute to an increased risk of colorectal cancer is reasonably consistent.

In addition to foods, the avoidance of the regular and heavy use of alcohol can contribute to lowering the risk of several cancers, including breast cancer in women, and oral, esophageal, liver, and laryngeal cancer. At least 3% of all cancers are attributable to alcohol consumption (4% of cancers in men and 2% in women). Alcohol acts synergistically with tobacco use to lead to more cancers than expected from the sum of risks associated with either factor separately.

Other measures under personal control in the prevention of cancer include the regular habit of physical activity and avoidance of overweight and obesity. Higher levels of physical activity have been associated with lower rates of certain cancers, including colorectal and breast. Obesity, defined as a body mass index over 30, has been associated with elevated risks of a large number of specific cancers in both men and women and may account for as much as 14% of all cancer in men and 20% of all cancer in women. The complex interaction of diet, overweight and obesity, and physical activity is one of substantial current investigation.

The avoidance of overexposure to the sun and ultraviolet light is also important, since it is clearly linked to both the common squamous and basal cell

skin cancers as well as to melanoma skin cancer, which can be fatal. Effective means of preventing ultraviolet light exposure include sun avoidance by seeking shade and using protective clothing as well as using sunscreens when in the sun. A false sense of security may reduce the protective effects of sunscreens if time in the sun is unintentionally extended beyond the protection offered.

Beyond personal choices and behaviors, other measures can lead to cancer prevention. Chemoprevention refers to the active use of agents, including pharmaceuticals or micronutrients, that may prevent cancer in various forms. For example, clinical trials have suggested that the use of inhibitors of cyclooxygenases (COX-2 inhibitors), which play a role in inflammation, apoptosis, and angiogenesis, may result in a reduced risk of colorectal and other cancers. Tamoxifen, an antiestrogen, is effective in preventing cancer in the contralateral breast of women who have had estrogen-receptor positive breast cancer as well as preventing cancer in women at high risk of breast cancer. Surprisingly, however, some of the best candidates for nutritional chemoprevention based on observational dietary studies have not proven effective as isolated agents. For example, although fruits and vegetables containing large amounts of carotenoids are protective, a form of vitamin A taken as a pill, beta-carotene, actually increased the risk of lung cancer among smokers. In addition, dietary fiber, which had been protective against colorectal cancers in case-control studies, has not been confirmed as a useful chemopreventive against colorectal adenomas, which are cancer precursors. Nevertheless, chemoprevention is likely to remain an important area of opportunity in cancer prevention. For example, promising trials of the role of selenium, soy protein, and finasteride in prostate cancer are in progress.

Cancer vaccines offer a new hope for the prevention of cancers of viral origin. Liver cancer is one of the most common and fatal cancers worldwide, and hepatitis B is the major causal agent. The chronic carrier state that frequently follows infection in newborn and young children can be prevented with hepatitis B vaccination given as close to birth as possible. In Taiwan, reductions in childhood rates of carcinoma of the liver have been observed since the introduction of the vaccine in 1984, but the results of contemporaneous controlled trials in other highly endemic countries are still awaited. For cervical cancer, a preventive monovalent HPV-16 vaccine against the human papillomavirus

has shown real promise against new, persistent infections in young women. If future studies confirm and expand this result, the impact of preventive vaccines on cervical cancer incidence and, therefore, on the need to rely on Pap smears for early detection, could be substantial in the near future.

What progress can be expected from reductions in occupational exposures to carcinogens and environmental pollution? Concerns about the causes of cancer present in our physical environment and beyond our direct control have become a persistent feature of the cancer prevention landscape. The role of some agents such as asbestos, ionizing radiation, vinyl chloride, benzene, and radon are well documented. To date, a total of 25 chemicals or chemical mixtures have been designated as carcinogens and another 25 as probable carcinogens by the International Agency for Research on Cancer. Yet estimates suggest that environmental toxins and occupational exposures account for no more than 5% to 7% of all cancers. The impetus for seeking regulatory control and elimination of these chemicals is that societies can take direct action to prevent cancer due to these causes and, in principle, no one should sustain risks of cancer from agents to which they are exposed involuntarily. The challenge remains to continuously explore new leads, to construct appropriate environmental protections, and to communicate clearly to the public what is known and yet unknown.

Gradients in overall cancer mortality by socioeconomic status exist in industrialized countries such that those on the bottom of the gradient sustain higher death rates. The understanding of these gradients through study of the role of known cancer risk factors, of health care delivery, and of the relevant biologic pathways is a new area of transdisciplinary research. Once understood, interventions may be developed at critical points in the pathways to cancer, including those at a policy and public health level. For example, we have good evidence that tobacco use can be reduced by changes in clean air laws, the price of tobacco, and efforts to reduce sales to youth.

In conclusion, what we already know can contribute mightily to the prevention of cancer. Many of the actions necessary are behavior or "lifestyle" factors accessible to individuals, but other interventions by health care systems and policies on a societal level can also be effective. Interventions of proven worth in both the clinical and public health setting have been reviewed by the U.S. Preventive Services Task Force

and the U.S. Guide to Community Prevention Services. Further research into the causes of cancer and the means to prevent it will provide more avenues for action in the future, but effective actions are at hand today.

## CANCER: PSYCHOSOCIAL TREATMENT

---

Although cancer continues to be a significant public health problem, considerable medical progress has been made in treating this set of diseases during the past several decades. Many forms are curable, and there is a sustained decline in the overall death rate from cancer in terms of the impact on the total

population. Because of improvements in medical science, more people are living with cancer than ever before. However, psychosocial and emotional needs are frequently overlooked, and in spite of improved medical prognoses, cancer patients often continue to experience significant emotional distress. For example, compared to the general population, cancer patients experience a fourfold increase in the rate of depression. Other significant psychological problems include pain, anxiety, suicide, delirium, body image difficulties, and sexual dysfunctions. Even for people who historically have coped well with major negative life events, cancer and its treatment greatly increase the stressful nature of even routine daily tasks.

In response to these significant negative psychosocial consequences, a variety of psychosocial interventions have been developed to improve the quality of life of cancer patients and impact positively on their psychological distress. Such approaches include educational interventions, cognitive-behavioral strategies, and group therapy approaches.

## EDUCATIONAL INTERVENTIONS

The major goal of educational interventions is to reduce cancer patients' distress and improve their sense of control that may be engendered by lack of knowledge and feelings of uncertainty. Patient education programs have involved a variety of venues, including written materials, films, audiotapes, videotapes, and lectures. The topics covered include technical aspects of the disease and its treatment, potential side effects, navigating the medical system, and the physician-patient relationship. Scientific evaluations of such methods report beneficial effects, such as decreases in depression and anxiety and increases in knowledge about cancer.

## COGNITIVE-BEHAVIORAL INTERVENTIONS

Cognitive-behavioral therapy (CBT) is an empirical approach that focuses on the interrelationships between behavior, thoughts, emotions, and biological events regarding mental health problems and medical symptom development and persistence. CBT, in this context, incorporates a wide array of intervention strategies that attempt to change those behavioral, cognitive, and affective variables that mediate the negative effects of cancer and its treatment. Many strategies under the CBT umbrella are theoretically based

on principles of respondent and operant conditioning, such as contingency management (e.g., changing the consequences of behavior to change the behavior), biofeedback, relaxation training, and systematic desensitization, whereas other strategies are more cognitive in nature and include techniques such as cognitive distraction, cognitive restructuring, guided imagery, and problem-solving therapy. Applications of CBT for cancer patients have addressed both specific negative symptoms (e.g., anticipatory nausea, pain), as well as overall distress and quality of life.

*CBT for anticipatory nausea.* Clinically, a negative side effect of chemotherapy is anticipatory nausea and vomiting. From a respondent conditioning conceptualization, this occurs when previously neutral stimuli (e.g., smells, colors, and sounds associated with the treatment room) acquire nausea-eliciting properties due to repeated association with chemotherapy treatments and its negative aftereffects. Investigations conducted in the early 1980s found various CBT approaches (e.g., progressive muscle relaxation combined with guided imagery, systematic desensitization) to be effective in reducing anticipatory nausea and vomiting. Systematic desensitization is a procedure whereby over repeated pairings of anxiety-provoking stimuli with a relaxation-inducing response, such stimuli lose their anxiety-engendering properties as feelings of relaxation, rather than tension, become associated with such events.

*CBT for pain.* Although conflicting evidence exists regarding their efficacy, CBT strategies that have been applied to reduce cancer-related pain include relaxation, guided imagery and distraction, and cognitive coping and restructuring. Cognitive coping and restructuring strategies teach individuals to change those negative thoughts and beliefs (e.g., "I'll never get better," "This is the absolute worst thing that can happen to me!") that evoke or intensify negative stressful reactions, such as pain and distress.

*CBT for emotional distress.* The majority of scientific investigations involving CBT interventions with cancer patients tend to address general goals of decreasing their psychological distress and improving their overall quality of life. For example, behavioral stress management strategies (e.g., relaxation training, guided imagery) have been found to be especially effective in achieving such goals. Guided imagery is a CBT strategy that provides structured means of focusing on pleasant (e.g., favorite vacation place) or mastery (e.g., scenes of successfully coping with distress)

images as a means of fostering a relaxation response. Moreover, multicomponent CBT protocols (i.e., combining several different CBT techniques) tend to be the norm. As an example, one seminal study conducted by psychiatrist Fawzy Fawzy and his colleagues included patients who were newly diagnosed with malignant melanoma. This 6-week intervention was comprised of four components: health education, behavioral stress management, problem-solving training, and group support. Six months after treatment ended, patients receiving this treatment program reported significantly lower levels of psychological distress. In addition, 5 years posttreatment, treated patients continued to show significantly lower levels of anxiety, depression, and total mood disturbance.

CBT-oriented interventions have also included family members in treatment as a means of enhancing the positive effects of this intervention. For example, Art and Chris Nezu, cognitive-behavioral clinical psychologists, and their colleagues provided training in problem-solving skills to cancer patients along with their family caregivers (e.g., spouse, adult son or daughter). Problem-solving therapy helps individuals to better cope with stressful life events by improving their ability to be optimistic, identify why situations are problems, generate a variety of possible solutions, make effective decisions as to which solutions to carry out, and monitor the consequences of implemented solutions. In this study, investigators found that including a significant other fostered improved well-being above and beyond the positive effects of problem-solving therapy alone.

## GROUP THERAPY APPROACHES

The potential strengths of group psychotherapy for cancer patients are threefold: (1) it can provide for a milieu in which people with similar experiences can provide emotional support to each other, (2) it is cost-effective for the patient, and (3) it is time-efficient for the mental health professional. However, research evaluating these approaches has provided limited evidence for their efficacy in reducing distress and improving psychological adjustment for cancer patients. Furthermore, the empirical literature suggests that group therapy programs that focus primarily on providing peer support and emphasize the shared expression of emotions are less effective than either educational protocols or programs teaching coping skills.

One seminal study in support of a “supportive-expressive” group therapy approach was conducted by David Spiegel, a psychiatrist, and his colleagues. Their investigation included women with metastatic breast cancer who participated in weekly group therapy sessions that fostered supportive interactions among the participants, encouragement to express one’s emotions, and discussion of cancer-related problems. Close to a year after treatment began, these cancer patients reported significantly less anxiety, depression, confusion, and fatigue, as well as fewer phobias and less maladaptive coping responses.

## EFFECTS OF PSYCHOSOCIAL INTERVENTIONS ON HEALTH OUTCOME

In addition to assessing the effects of psychosocial interventions on psychosocial variables (e.g., emotional distress), investigators have also been interested in whether such interventions have any impact on health outcome; for example, do they actually affect the course or prognosis of the disease? This interest emanates from other research demonstrating that certain psychosocial variables, such as effective coping and positive social support, have been found to be associated with enhanced survival. Psychosocial treatments may affect the course of cancer by (a) improving patient self-care (e.g., reducing behavioral risk factors), (b) increasing patients’ compliance with medical treatment, and (c) influencing disease resistance regarding certain biological pathways, such as the immune system.

To date, the literature providing answers to this question remains equivocal, that is, some studies provide data supporting the notion that psychosocial interventions extend the life of cancer patients, whereas other investigations found no effect on survival. In addition to conflicting evidence, the existence of scientific problems across many of these types of investigations further add to the tentativeness of any firm conclusions in answering this question.

## EFFECTS OF PSYCHOSOCIAL INTERVENTIONS ON IMMUNE FUNCTIONING

One possible mediator of the positive effects of psychosocial interventions on improved health, as well as emotional well-being, is the immune system. In part, support for this hypothesis emanates from research showing changes in certain measures of

immune functioning in humans experiencing stressful events, as well as studies demonstrating changes in immune functioning as a result of receiving psychosocial treatment. For example, psychological-based interventions have been found to increase large granular lymphocytes, natural killer cells, and white blood cell numbers, all markers of improved immune functioning. Although research investigating the link between immunologic parameters and psychosocial variables in cancer patients is in its nascent stage, and therefore can only be viewed as suggestive in nature at this time, such a framework provides for one exciting area for future research and a possible means of explaining one pathway between behavioral factors and cancer-related health outcome.

## PREVENTION ISSUES

The above interventions have addressed goals of improved health and mental health factors *after* a person is diagnosed with cancer. However, treatment strategies can also affect behavioral risk factors, thus attempting to *prevent* cancer. Some of the cancer-related behavioral risk factors include smoking, alcohol, diet, and sun exposure. Overviews of the treatment literature concerning some of these behaviors are contained in other sections of this encyclopedia and therefore are not repeated here. With regard to sun exposure, some interventions have led to increased knowledge of skin cancer and awareness of protective measures; however, programs have had only limited success with increasing preventive behaviors in at-risk groups.

Prevention strategies are also important for individuals considered at high risk due to genetic and familial factors. For example, a positive family history of breast cancer is an important risk factor for breast cancer in women. As such, first-degree relatives of women with breast cancer may also be at risk for psychological distress. With this in mind, investigators have successfully developed programs to reduce this distress and to increase the rate of mammography testing among this group.

## SUMMARY

Overall, research has amply demonstrated that a variety of psychosocial interventions are effective in reducing specific cancer-related physical (e.g., pain, nausea, and vomiting) and emotional (e.g., depression,

anxiety) symptoms, as well as enhancing the overall quality of life of cancer patients. Such treatment programs include educational interventions, a wide array of cognitive-behavioral interventions, and group psychotherapy programs. Among these various approaches, CBT interventions have been more often the focus of scientific investigations and thus have tended to emerge as the more effective and versatile overall therapeutic approach.

In addition to improving cancer patients' emotional well-being, research suggests that psychosocial interventions can also lead to improved survival by affecting the course of the cancer itself. One biological pathway that has been identified as a potential mechanism by which this can occur is the immune system. However, additional studies have noted a lack of an effect on survival rates as a function of participating in psychosocial treatment. Moreover, the literature providing evidence to support a link between behavioral variables and health outcome as mediated by the immune system is only in its infancy with regard to cancer. Therefore, substantial additional research is necessary before the nature of these relationships can be clearly elucidated.

Psychosocial interventions have also been developed for at-risk groups (e.g., first-degree relative of a woman with breast cancer) or people engaging in risky cancer-engendering behaviors (e.g., excessive sun exposure) as a means of reducing risk and preventing cancer.

## CANCER SCREENING

---

Cancer is evident in virtually every country of the world, with developed countries having a greater incidence of disease than nondeveloped countries. The American Cancer Society reports that in the United States alone, cancer accounts for one in four deaths every year, with mortality rates being disproportionately high among ethnic minority populations. The aim of screening is to detect the presence of disease in asymptomatic individuals, thus managing the disease at a more treatable stage. Cancer mortality rates in this country have been considerably reduced with the advent of effective early detection screening regimens, notably mammography for women 50 years and older (breast cancer), Pap smears (cervical cancer), and fecal occult blood testing (FOBT; colorectal cancer). These types of established screening guidelines have frequently been implemented after extensive debate regarding whether screening would prolong life among specific populations (e.g., mammography in women under 50 years of age). Currently, the utility of a number of other procedures is under investigation, including prostate specific antigen (PSA; prostate cancer), CA125 and transvaginal ultrasound (ovarian cancer), flexible sigmoidoscopy and colonoscopy (colorectal cancer), and spiral computed tomography (spiral CT; lung cancer). While the ultimate utility of screening is unclear, it remains the only feasible and recommended population-based approach for early cancer detection.

Effective screening calls for long-term adherence to recommended guidelines over the life cycle. However, there are a number of extrinsic and intrinsic factors that influence cancer screening behaviors and may serve as barriers to sustained adherence. From the extrinsic perspective, access to care is the major determinant of screening attendance, particularly among low-income, ethnic minority, elderly, and rural populations. Inadequate or no health care insurance, geographic isolation, lack of transportation and child care, and availability of medical interpretation services for non-English-speaking individuals are important

barriers to care. A number of intervention approaches have been implemented that directly address access-related barriers to screening attendance. Programs that improve access to screening facilities (e.g., mobile screening services, provision of child care assistance, transportation to screening units), minimize language barriers, and provide culturally sensitive services have proven effective in enhancing screening utilization.

However, while interventions to enhance access have been shown to improve screening adherence, in many cases the barriers to adherence are also centrally related to factors intrinsic to the individual, namely psychosocial factors, particularly over the long term. We now review the psychosocial factors influencing screening adherence and discuss the importance of targeted psychosocial intervention protocols, tailored to assess and address these barriers, in promoting sustained screening adherence.

### PSYCHOLOGICAL FACTORS INFLUENCING SCREENING ADHERENCE

The Cognitive-Social Health Information Processing (C-SHIP) model provides a framework for understanding the cognitive, emotional, and social factors that influence cancer screening behaviors. According to the cognitive-social model, key determinants of cancer screening behaviors include the individual's (a) cancer-related knowledge and perceptions of cancer vulnerability, (b) expectancies and beliefs about cancer risk and available courses of action, (c) health-related values and goals, (d) cancer-related distress, and (e) coping skills for managing distress and generating action plans for adherence to screening and follow-up health-protective behaviors.

#### Cancer-Related Knowledge and Risk Perceptions

Reluctance to participate in cancer screening programs is related, first and foremost, to lack of cancer awareness. Lack of knowledge about the etiology of cancer and available screening options is widespread among both average-risk and high-risk populations. Groups showing particularly low rates of cancer screening, including lower income, less educated, rural, and inadequately insured individuals (such as Native Americans, African Americans, Hispanics, the elderly), show particularly low levels of cancer-related knowledge.

Inaccuracies in knowledge are associated with misperceptions about one's cancer risk. Studies show that

some individuals consistently underestimate their risk for cancer, while others overestimate their risk. Furthermore, subjective risk perceptions tend to vary with cancer type. In particular, men at risk for prostate cancer tend to underestimate their risk, whereas women at risk for breast cancer tend to overestimate their risk. Risk perceptions also vary according to the way in which they are measured (e.g., as an estimate of the percentage lifetime likelihood of developing cancer, ranging from 0% to 100%, or as a Likert scale, ranging from very low likelihood of developing the disease to very high). Not surprisingly, subjective risk levels show a poor correlation with objective risk levels.

### Cancer-Related Expectancies and Beliefs

Perceived benefits (i.e., pros) and limitations (i.e., cons) about cancer screening are associated with adherence. When the expected pros of cancer screening are emphasized (as when the physician recommends the screening procedure), participation rates are increased. Hence, screening rates are higher (although still less than optimal) in cases where there are clear consensus guidelines (e.g., mammography, Pap smear, and FOBT), and lower where consensus guidelines are not clearly established (e.g., PSA for prostate cancer, skin cancer screening). In addition, ambivalent attitudes toward screening utilization among providers and consumers tend to act as barriers to adherence, and may relate to the public debates that have taken place about the efficacy of these procedures. Rates of adherence may also depend on the individual's level of objective cancer risk, such that increased risk leads to increased screening utilization, most likely as a result of greater physician advice.

Conversely, perceived barriers (e.g., negative beliefs about the efficacy or aversiveness of the diagnostic procedure) have been consistently associated with reduced screening adherence. For example, screening adherence rates are lower in cases where the procedures are either unpleasant or associated with discomfort (e.g., FOBT, sigmoidoscopy and colonoscopy for colorectal cancer screening). A related expectancy factor, perceived lack of confidence to perform the procedure, is also associated with low levels of screening adherence, particularly in the case of self-examination procedures that require the individual to personally execute the behavior (e.g., skin self-examination and breast self-examination).

An interesting finding is that cancer screening and diagnostic follow-up adherence among elderly

individuals is considerably lower than for their younger counterparts. Given that the efficacy of widely used screening methods, such as mammography, has not yet been determined for individuals over the age of 65, uncertainty about the efficacy of cancer screening among physicians and patients may contribute to lower adherence among this age group.

### Cancer-Related Values and Goals

Cancer-related values include fatalistic beliefs (i.e., believing, for instance, that there is no use in getting screened, since cancer is inevitable). These types of beliefs are prevalent among ethnic minorities, particularly those who are lower income, less well-educated, and unemployed. Individuals with greater fatalistic beliefs report significantly lower levels of adherence to cancer screening. Furthermore, culturally specific values associated with shame, preferences for non-Western medicine, and mistrust of health professionals have been identified as barriers to cancer screening adherence. These types of shared cultural values tend to reduce expectations about the utility of cancer screening, thereby reducing the motivation for an individual to adhere to these recommendations over the long term.

Certain shared cultural values appear to have a beneficial effect on cancer screening behaviors. Joan Bloom, from the University of California, reports that family members can support screening behaviors by acting as a cultural symbol of the reason to stay healthy. The family's support of the individual's attempts to maintain recommended cancer screening regimens is especially important among cultures placing a high value on interdependence, and most evident for initial cancer screening and highly invasive tests (e.g., sigmoidoscopy). Thus, appealing to family membership may be an effective means of facilitating cancer screening adherence among highly interdependent families, particularly in the case of unfamiliar or uncomfortable tests.

Media exposure represents an additional factor likely to directly influence shared screening-related values and goals and, hence, screening adherence. Breast and cervical cancer screening (which are associated with better adherence) have received a high degree of media attention over the last few decades, but colorectal cancer screening (which is associated with poorer adherence) has received little publicity.

### Cancer-Related Distress

Cancer-related distress refers to the situation-specific (i.e., state) anxiety, worry, and intrusive thoughts that may arise in response to a cancer threat. The effect of cancer-related distress on screening adherence differs according to the level of distress experienced. In the case of low levels of worry, cancer-related concerns are not activated, so there is no motivation for initiating and sustaining screening behaviors. For example, low levels of cancer worry among the elderly, who tend to believe they are no longer vulnerable to cancer, have been linked with poor screening adherence. In contrast, in the case of high levels of worry, excessive anxiety activates avoidance that can undermine the individual's intentions to adhere to recommended screening regimens. For example, among ethnic minorities, fear of cancer is reported as one of the most important reasons for not participating in screening programs and for not attending diagnostic follow-up (e.g., colorectal, cervical). Fear of the procedure itself also undermines screening and follow-up diagnostic adherence, particularly concerns and fears about the iatrogenic effects of biopsies and repeat x-rays among individuals recalled for further diagnostic investigations.

Research by Suzanne Miller and colleagues at Fox Chase Cancer Center in a number of cancer-risk contexts indicates that individuals need to be made sufficiently aware of the cancer threat to motivate them to participate in screening regimens, but should not become so anxious that they actively avoid screening participation. Fear of cancer should also be contained so that it does not lead to overuse of screening, as in the case of excessive performance of breast cancer self-examination that is sometimes found among high-risk women.

### CANCER-RELATED SELF-REGULATORY SKILLS

To effectively adhere to cancer screening regimens, individuals must be able to manage cancer risk-related distress and to develop specific action plans for carrying out health-related behaviors (e.g., scheduling an annual cancer screening examination). Individuals who prefer one form of cancer screening and who generally have health-protective behaviors (e.g., exercise, healthy eating, cholesterol check) appear to be more likely to participate in other forms of cancer screening. This pattern suggests that the individual

has available a general set of self-regulatory skills for managing cancer- and disease-related distress and for executing effective action scripts for maintaining recommended health-protective behaviors.

Consistent with this analysis, screening adherence is influenced by the type of procedure, that is, medical examination regimen versus self-examination regimen. Medical examination is carried out by medical practitioners, and includes direct observation (e.g., skin, cervix), palpation for detecting lumps or tumors (e.g., breast, prostate, rectum), and procedures such as endoscopy, x-rays, magnetic resonance imaging (MRI), or ultrasound for internal cancers (e.g., stomach, colorectal). In contrast, self-examination is performed by the individual and includes direct observation (e.g., skin cancer check) and palpation (e.g., breast self-examination).

For individuals to effectively carry out self-examination procedures, they must have in place strategies for managing cancer risk-related distress and for developing specific action plans for carrying out the required health-related behaviors. Not surprisingly, adherence rates are highest for procedures that are based solely on medical examination procedures (e.g., Pap smear and mammography), and thereby require relatively fewer self-regulatory skills. In contrast, rates are lowest for procedures that require the individual to enact and sustain the behavior (e.g., for colon cancer, since the individual must collect three separate fecal specimens for laboratory analysis). This differential pattern of adherence is also evident within a particular cancer type. For example, adherence to mammography and clinical breast examination (procedures conducted by a medical professional) far exceed adherence rates to breast self-examination (a self-initiated screening procedure).

### PSYCHOSOCIAL INTERVENTIONS TO FACILITATE CANCER SCREENING ADHERENCE

In sum, the effectiveness of cancer screening regimens rests upon long-term adherence. However, even among well-established cancer screening regimens (e.g., breast, cervical), adherence is less than ideal. Effective screening adherence requires that individuals be knowledgeable about their cancer screening options, believe that the pros of cancer screening outweigh the cons, have values consistent with the belief that cancer screening is a useful tool for reducing cancer mortality, and have a moderate level of cancer-related

distress and perceived vulnerability sufficient to maintain (but not overwhelm) self-regulatory strategies for long-term adherence. In addition to improving access to care, these psychosocial factors need to be taken into account in a coordinated fashion when designing interventions to promote performance of cancer screening behaviors.

The most effective intervention protocols are those that are carefully targeted to the specific audience (e.g., ethnic or cultural group), and systematically tailored to the individual's profile of cognitions and affects that become activated in the processing of cancer-relevant information. The use of preparatory counseling strategies that assess and address cognitive-affective barriers to diagnostic follow-up adherence has been found to be beneficial in enhancing participation in several cancer screening contexts (e.g., prostate, cervical, breast). For example, research conducted by Suzanne Miller and colleagues has explored the utility of a tailored preappointment telephone counseling intervention targeted to low-income minority women who need to undergo diagnostic follow-up following notification of an abnormal Pap smear. The counseling intervention addressed the individual's cognitive (i.e., inadequate knowledge, misperceptions of risk, inaccurate expectancies), affective (i.e., distress levels, anticipated discomfort), and self-regulatory (i.e., poor planning) barriers to adherence. Patients who received telephone counseling displayed significantly higher adherence rates to the initial follow-up screening appointment after feedback of the abnormal test result in comparison with patients who received a telephone appointment reminder call and in comparison with usual care. Furthermore, the effects of the intervention were not only evident in the short term but were also sustained over the long term (i.e., at the 6-month follow-up screening appointment). In addition to traditional counseling approaches (e.g., telephone counseling, print materials), recent technological developments will allow for the development of especially promising innovative approaches to enhancing screening adherence through the use of new media approaches (e.g., interactive Internet- and CD-ROM-based interventions).

A key factor that needs to be considered when designing intervention protocols is the role of stable, preexisting individual differences in the pattern of response to health-related information. According to the cognitive-social model, individuals are characterized by distinctive cognitive-affective signatures that determine their characteristic profile of responses to

cancer risk feedback. High monitors (who typically attend to and scan for health-related messages) are more likely to respond to health threats with heightened perceptions of their own vulnerability, greater risk-related distress, and poorer management of anxiety. In contrast, low monitors (who distract from and ignore health-related messages) are more likely to demonstrate inadequate cancer-related knowledge, lowered risk perceptions, and poor planning. These two response styles have implications for the design of tailored counseling and communication messages. High monitors fare better with voluminous information that reduces uncertainty, promotes reassurance, and manages risk-related distress. Low monitors, on the other hand, benefit most from interventions that increase the salience of threat and provide cues and prompts for action.

## SUMMARY

In spite of recent technological advances in cancer control, adherence to available cancer screening regimens continues to fall below optimal levels. Barriers to adherence include lack of access to care, cognitive factors (i.e., cancer-related knowledge, perceived vulnerability, expectancies and beliefs about cancer risk and available courses of action), social factors (i.e., cancer-related values and goals), and affective factors (i.e., cancer-related distress and self-regulatory strategies to manage distress and to execute effective action scripts for maintaining screening recommendations over the long-term). Psychosocial interventions carefully targeted to the population group and tailored to the unique cognitive-affective profile and response style of the individual, combined with access-enhancing approaches, appear most promising.

## CANCER AND SMOKING

---

Tobacco use is the largest preventable cause of cancer death in developed countries and is responsible for approximately 30% of the cancer mortality that occurs in the United States. Cigarette smoking, in contrast to other forms of tobacco use, developed largely during the 20th century, and it is cigarette smoking that is responsible for the epidemic of lung cancer that began during the 1930s and continues into the new millennium. Cigarette smoking currently causes more than three quarters of the cancer of the lung, oral cavity, larynx, and esophagus in the United States, and it is also responsible for approximately one third to one half of the cancer of the kidney, urinary bladder, and pancreas. Of the cancers caused by cigarette smoking, lung cancer is responsible for the majority of the cancer deaths and is the largest cause of cancer death in both males and females.

Continued investigation of the relationship between cigarette smoking and cancer has produced evidence of a causal relationship between cigarette smoking and cancers of the stomach, cervix, and acute myeloid leukemia. Evidence also suggests that there may be a modest increased risk of colorectal cancer and cancer of the liver. Cigarette smoking does not appear to increase the risk of cancer of the breast. Cigarette smokers have lower rates of endometrial cancer, but the effect seems to be limited to postmenopausal women.

Tobacco smoke is a complex aerosol with more than 4,800 individual constituents, of which at least 58

have been identified as carcinogenic. Most of the carcinogenic effects of tobacco smoke are contained in the particulate phase of cigarette smoke. The small particle size of the smoke aerosol leads to extensive deposition of smoke particles in the airways and alveoli of the lung. Dysplastic and metaplastic changes are commonly present in the cells lining the airways of long-term cigarette smokers, and the extent of these changes are correlated with the intensity and duration of smoking behavior. Similar changes have also been noted in the larynx. The polycyclic aromatic hydrocarbon and tobacco specific nitrosamine carcinogens in smoke form DNA adducts that lead to persistent miscoding during replication. Miscoding errors occur as mutations in genes critical for tumor suppression and lead to the formation of oncogenes. Continued accumulation of molecularbiologic injury over time in long-term smokers can ultimately transform normal cells into a malignancy.

The risk of developing cancer from cigarette smoking increases with the intensity and duration of the smoking behavior, with duration having a more powerful effect on risk. Approximately 40% of persistent cigarette smokers will die prematurely due to smoking-induced disease, and, among heavy smokers, more than 25% are likely to die of a smoking-induced malignancy.

There is little evidence that nicotine by itself is carcinogenic, but nicotine is addictive for most cigarette smokers, and the carcinogenic constituents in tobacco tar are an obligatory companion to the dose of nicotine needed by smokers to satisfy their addiction. Nicotine addiction is manifest by a need for repetitive dosing throughout the day. Once established, the pattern of smoking frequency is a relatively consistent number of cigarettes smoked per day for individual smokers, but the number of cigarettes smoked per day varies widely across the population of smokers, leading to a substantial variation in the cancer risk among individual smokers.

Cancer risks from smoking pipes and cigars are similar to those of cigarette smokers for cancers of the oral cavity and larynx, but the risks for lung cancer are much lower. This difference is likely a result of differences in extent of inhalation with use of these different forms of tobacco. The more alkaline smoke generated by burning pipe and cigar tobacco allows nicotine to be easily absorbed across the oral mucosa, and smokers who have used only these products tend not to inhale smoke into the lung. The more acidic smoke from cigarette tobacco protonates the nicotine, making oral absorption more difficult. Cigarette smoke must then be inhaled into the larger absorptive

surface of the lung in order for substantial amounts of nicotine to be absorbed, and this leads the vast majority of cigarette smokers to inhale the smoke. Unfortunately, cigarette smokers who switch to smoking cigars are likely to continue inhaling, negating any potential benefit of switching.

The addition of filters to cigarettes, and other changes that have lowered the machine-measured yield of tar and nicotine, were expected to reduce the risk of smoking by reducing the exposure of smokers to smoke. However, smokers compensate for the reduced nicotine delivery of these cigarettes by increasing the size and intensity of their puffing on the cigarette and by smoking more cigarettes per day, negating any potential reduction in smoke exposure from so-called lower tar products. Risks of developing cancer do not differ by type of cigarette smoked. The evidence does not support a recommendation that smokers shift to smoking cigarettes with lower machine-measured yields of tar and nicotine as a means of reducing cancer risk, and such a recommendation can cause harm if it misleads smokers to postpone serious efforts at cessation.

Cessation of cigarette smoking reduces the risk of developing cancer in comparison to continuing to smoke. Manifestation of this risk reduction is delayed by one or more years due to the interval between malignant transformation at the cellular level and the time when a cancer is first clinically detected. Cessation of cigarette smoking will reduce the rate of malignant transformation but has less effect on the likelihood of a cancer being clinically detected once malignant transformation has occurred. Growth from a single cancer cell to a clinically detectable cancer may take several years, and it is only after these cancers have been detected that a reduction in the rate of malignant transformation will translate into a reduction in cancer incidence or death rates.

Lung cancer rates fall to approximately one half of the rates of continuing smokers after approximately 10 years of abstinence, and they continue to fall as the duration of abstinence becomes longer. However, even after 20 years of abstinence from smoking, lung cancer risks remain about twice those of individuals who have never smoked.

## CARDIAC REHABILITATION

---

Cardiac rehabilitation refers to the process of providing exercise training, medical management for coronary risk factors, and psychosocial interventions for individuals who have cardiovascular disease. Persons eligible are those who have had a heart attack, heart surgery, or other invasive heart procedures such as coronary artery stenting. In addition, persons with congestive heart failure, arrhythmias, implantable defibrillators, valvular heart disease, or peripheral vascular disease qualify for these services. Cardiac rehabilitation programs were first developed in the 1950s when it became apparent that hospitalization for 2 weeks or longer, which at the time was considered necessary for patients who had had heart attacks, led to significant physical deconditioning. The early rehabilitation programs started in the hospital and then continued in community-based group programs or at home. Concern about the safety of unsupervised exercise after discharge led to the development of hospital-based programs, usually supervised by physicians and specially trained coronary care

nurses. Hospital-based programs usually included electrocardiographic monitoring of the patients during exercise.

Hospitalization for heart disease, including bypass surgery, stenting procedures, and other invasive therapies, has now been shortened to 3 to 5 days, resulting in minimal physical deconditioning. However, significant evidence has shown that regular exercise, modification of diet, cessation of tobacco use, and the use of medications to reduce serum lipids, blood pressure, clot formation, and stress on the heart significantly reduce the chance of future cardiovascular events in patients who have heart disease. Cardiac rehabilitation services are critical in filling this important role of education and clinical monitoring. Other evidence suggests that depression and other psychosocial factors, such as sustained anger and hostility and social isolation, may increase the risk of subsequent heart attacks in patients with heart disease. Cardiac rehabilitation programs are ideal settings in which to provide both short- and long-term psychosocial interventions. Cardiac rehabilitation programs also play a role in preparing patients for return to work and resumption of sexual activity.

## GUIDELINES

In recognition of these potential contributions to rehabilitation, in 1994 the Agency for Health Care Policy and Research (now called the Agency for Healthcare Research and Quality), the nation's leading federal agency for research on health care quality, costs, outcomes, and patient safety, convened a group of experts to critically review the scientific literature with the goal of developing evidence-based clinical practice guidelines for cardiac rehabilitation. The report recommended that cardiac rehabilitation programs should consist of multifaceted and multidisciplinary approaches to overall cardiovascular risk reduction and that programs that consist of exercise training alone are not considered cardiac rehabilitation. More recently, the American Heart Association and the American Association of Cardiovascular and Pulmonary Rehabilitation (AHA/AACVPR) stated that all cardiac rehabilitation/secondary prevention programs should contain specific core components that aim to optimize cardiovascular risk reduction, foster health behaviors and compliance to these behaviors, and promote an active lifestyle for patients with cardiovascular disease. The conclusions and recommendations were derived

from an extensive and critical review of the scientific literature pertaining to cardiac rehabilitation, as well as from the expert opinions of the panel.

The need for cardiac rehabilitation is substantial. In 1997, acute myocardial infarction (MI) was diagnosed in over a million people in the United States, and 800,000 patients underwent coronary artery bypass surgery. An estimated 13.5 million U.S. citizens have heart disease, many of whom are severely limited by their symptoms. Yet less than 20% of appropriate candidates in the United States currently participate in formal programs. The data for women and minorities suggest that individuals are even less likely to be referred and/or participate.

## Exercise

Two main symptoms of coronary heart disease, chest discomfort and shortness of breath on exercise, are related to a number of factors, including the extent of coronary atherosclerosis and the presence and/or extent of permanent myocardial damage. When the demand for oxygen in the heart muscle is greater than the supply, worsened symptoms or even new heart attacks can occur. Cardiac rehabilitation programs have developed methods, such as use of symptom-limited exercise treadmill testing, to determine safe exercise limits for patients. Treadmill testing involves challenging a patient with an increasing workload on a treadmill (or a stationary bicycle). The rate and slope of the treadmill are gradually increased while the patient's vital signs and symptoms are monitored. This test provides information as to the presence or absence of a critical lack of blood flow to the heart muscle, the ability of the heart to safely meet the demands of increasing exercise without signs of heart failure. In addition, the heart rate and blood pressure at which abnormal symptoms occur can be determined. This information can then be used to develop safe exercise recommendations.

Historically, walking and stationary bicycling have been the preferred forms of exercise. In general, patients exercise at 65% to 85% of the maximum safe heart rate observed during the exercise treadmill test and at a frequency of two to four times a week for 30 to 45 minutes per session. The length and intensity of the exercise is increased as patients become more conditioned. Patients with more severe heart disease may wear a heart rate monitor as they exercise. As a result of careful assessment and monitoring, coronary events

in rehabilitation settings have become very low, less than 1 per 100,000 hours of patient exercise.

Exercise following a heart attack, surgery, or procedures has a number of benefits. Controlled trials of exercise after MI have demonstrated reductions in subsequent cardiac events and death from cardiovascular diseases. A study combining results from a number of studies found that participation in cardiac rehabilitation was associated with about a 25% reduction in overall mortality and mortality from cardiovascular causes over 3 years. However, most of the participants in these studies were men under age 65, and the studies were also done before many of the modern effective medical treatments were in widespread use. As most cardiac rehabilitation patients are 65 years or older and more women have begun to use these services, the results from earlier studies must be interpreted with caution. Regular exercise may also help provide favorable changes in how blood vessels function, may lower serum lipids, reduce blood clotting, and improve the balance between sympathetic and parasympathetic activities on the heart. Such small favorable changes across multiple systems may have benefit, whereas the individual changes by themselves are unimportant. Regular exercise also improves mood in depressed post-MI patients and may reduce anxiety and have other benefits. Finally, exercise testing and exercise may help evaluate patients' physical ability to return to work and resume sexual and other activities.

Cardiac rehabilitation programs usually include a medical director, an exercise physiologist, a nurse, dietician, and sometimes a mental health worker. Many programs are provided in hospital-based or community-based exercise facilities, but home-based programs have been shown to be equally effective. Some programs enroll patients for 6 months or less, while others provide ongoing services.

### Multifactorial Risk Reduction

Modern rehabilitation programs provide interventions to reduce a patient's risk of a subsequent cardiac event. The main lifestyle-related risk factors for a recurrent cardiac event are high levels of serum lipids, obesity, hypertension, diabetes, the use of tobacco, lack of regular physical activity, social isolation, and depression. Addressing two or more risk factors at a time is called multifactorial risk reduction.

High levels of blood lipids increase the risk of heart disease. Reduction in lipids reduces the rates of

subsequent heart attacks. Lipid lowering generally involves adoption of a low saturated fat, low cholesterol diet, weight loss, and the use of medications that alter the body's synthesis or absorption of various lipids. Although such combined interventions are effective in reducing lipid levels to very low levels, recent studies in clinical practice find that few patients meet the AHA or American College of Cardiology (ACC) target goals.

Weight loss also reduces cardiovascular risk, in part by reducing blood pressure and lipids. Exercise alone has little effect on weight loss, but when combined with dietary interventions may reduce the body mass index, a measure of how much a person weighs adjusted for height, by 4% to 9%. Cardiac rehabilitation programs usually have the personnel and programs to help participants adopt and maintain a low saturated fat, low cholesterol diet and reduce caloric intake.

Cardiac rehabilitation programs have also been very effective in helping patients with heart disease stop using tobacco. Many smokers will stop using tobacco following an acute MI. The most effective programs have included a strong recommendation by a physician to stop smoking, with interventions managed by a nurse during hospitalization and follow-up.

Other important risk factors include reducing blood pressure levels in the hypertensive individual, controlling blood glucose levels in individuals with diabetes, and the routine use of small doses of aspirin and drugs such as propranolol to protect the heart muscle during overexertion.

Risk factors are interactive and multiplicative. For instance, having both high blood cholesterol and smoking increases the risk of subsequent heart attacks more than if the two single risks were summed. Thus, multifactorial risk reduction programs are particularly important. A multifactorial risk-reduction program that combined intensive behavioral modification and medications resulted in a 30% reduction in saturated fat intake, a 4% reduction in BMI, a 22% reduction in LDL cholesterol (the "bad" cholesterol), 23% increase in HDL (the "good" cholesterol), and 20% improvement in exercise capacity. These improvements were associated with a decrease in the rate of atherosclerotic disease progress as well as in the rates of major clinical cardiac events and hospitalization.

Most cardiac rehabilitation interventions occur within the first 6 months of a heart attack, surgery, or

procedures. While the short-term effects are beneficial, a significant issue is the maintenance of risk-reduction changes that can be sustained for many years. Atherosclerosis is a progressive disease process requiring life-long attention to an active, healthy lifestyle.

### Psychosocial Aspects of Rehabilitation

Recovery from a heart attack, heart surgery, or other cardiovascular procedures involves a number of psychosocial aspects that are positively affected by rehabilitation. Patients who have had a life-threatening cardiac event find significant relief when they are able to exercise and resume their usual activities. Measures of anxiety, emotional stress, lack of self-confidence, depression, social isolation, and quality of life all improve after rehabilitation, although it is difficult to demonstrate that the changes are specific to cardiac rehabilitation.

Many studies have now shown that depression and social isolation after a coronary event are associated with increased morbidity and mortality rates. A recent large, multicenter study, involving nearly 2,500 men and women followed for up to 4 years following their heart attacks, found no differences in morbidity and mortality in depressed and/or socially isolated patients who were provided cognitive-behavioral therapy to improve mood and reduce social isolation compared to patients who received usual care. Depression improved significantly in both groups, resulting in small differences in measures of depression between treatment and control, which might have obscured potential benefits.

Most cardiac rehabilitation programs include stress management programs and programs designed to reduce anger and hostility. Although the effect of these programs on subsequent cardiovascular morbidity and mortality remains controversial, they are well received by patients.

One of the major benefits of cardiac rehabilitation programs has been in helping patients return to work and resume other customary activities. Twenty years ago, it was not uncommon for patients who had had a heart attack to stop working altogether or delay returning to work for many months. With modern medical therapies and exercise stress testing, most patients can safely return to work, resume sexual activity, and engage in customary leisure activities very soon after their return home from the hospital.

### Case Example

A 58-year-old man joined a cardiac rehabilitation program 3 weeks after discharge from the hospital following an acute MI. A lifelong smoker, he had been counseled to stop smoking while in the hospital and was able to do so upon discharge. On the initial evaluation in an outpatient cardiac rehabilitation program run by the YMCA, he was found to have elevated lipid levels, mild obesity, and was quite concerned that he might have a heart attack even with mild exercise. He also wanted to know when he could safely return to work. He underwent an exercise treadmill test that suggested he could safely exercise at a heart rate of 120 beats per minute. He was put on an exercise schedule that included group exercise as well as instructions to walk 30 minutes every other day at home. While not at exercise class, he was instructed to keep a diary of his exercise, including any symptoms he experienced during exercise. His doctor was contacted and he was started on a lipid-lowering medication. He was told that, based on the type of work he did and his treadmill results, he could return to work as soon as he wanted. He met with a dietician to receive recommendations for his diet and for weight loss, and with a nurse to review his medications and cardiovascular symptoms. Following the initial assessment and meeting with the physician, he participated in the group program for 3 months. After this period of time, the nurse maintained contact with him by phone once every other week for the next 3 months. During one of these phone calls, she noted that he missed a number of his medication doses and she recommended a simplified medication schedule. He continued to increase his exercise frequency and intensity until he was jogging 4 times a week for 30 to 40 minutes. He returned to work 6 weeks after his heart attack. After 4 months, his lipid levels had improved but not to the targeted levels. His physician was contacted and new medication was added. After 6 months, he was discharged from the program.

## CARDIOVASCULAR DISEASE PREVENTION: COMMUNITY-LEVEL INTERVENTIONS

---

In the early 1970s, death rates from cardiovascular diseases (CVD) peaked in the United States; 499 of every 100,000 people died in 1973 from CVD, the leading cause of death for women and men across all racial/ethnic groups. The first major response to the CVD epidemic was initiated in the 1960s and was based on a medical model approach that focused on the identification and treatment of high-risk and moderate-risk patients. Federally funded research studies conducted during this era included the Veteran's Administration Cooperative Study, the Hypertension Detection and Follow-Up Program, the Lipid Research Clinic's Study, and the Multiple Risk Factor Intervention Trial. The medical model approach was unsuccessful in decreasing the number of new cases of CVD because most CVD actually occurs among the large number of individuals who are at relatively low risk. Although such individuals are at low relative risk, they contribute significantly to the population's attributable risk because of the widespread prevalence of CVD risk factors.

The second major response to the CVD epidemic, initiated in the late 1970s, was based on a primary prevention, or public health, model that sought to change the distribution of risk factors among individuals at the community level. This approach

was supported by evidence from clinical trials and prospective studies that clearly demonstrated that small changes in risk factors at the population level yielded greater reductions in rates of CVD than larger changes at the individual level. From 1978 to 1990, the following three comprehensive community-based CVD prevention trials were conducted with federal funding:

1. The Stanford Heart Disease Prevention Program (SHDPP), also known as the Five-City Project, included two intervention and two control cities in California (a third control city contributed only morbidity and mortality data) (Farquhar et al., 1985).
2. The Minnesota Heart Health Program (MHHP) included three intervention and three control cities in Minnesota and the Dakotas (Blackburn et al., 1984).
3. The Pawtucket Heart Health Program (PHHP) included one intervention city in Rhode Island and one control city in Massachusetts (Carleton, Lasater, Assaf, Lefebvre, & McKinlay, 1987).

Each of these trials simultaneously addressed the prevention and treatment of the known and modifiable risk factors for CVD; hypertension, cigarette smoking, high dietary fat, obesity, and sedentary lifestyle. Each intervention city received a comprehensive multifactor risk reduction education program that lasted from 5 to 8 years.

The risk reduction education programs used in these three trials were designed to facilitate the adoption of health practices, including direct education of health professionals and the public through media and personal contact as well as community organization to foster institutional and environmental support. Each trial integrated individual and social change approaches, employing some combination of social learning theory, social network diffusion theory, and social marketing to guide the intervention. Although the theoretical underpinnings were similar, the trials differed in their application of theory to the design of educational programs. SHDPP used television, radio, and print materials to target behavior change. MHHP emphasized face-to-face communications, public events, and television. PHHP focused on community organization, campaigns, screening counseling, and referral activities.

The results of each trial have been published (Carleton, Lasater, Assaf, Feldman, & McKinlay,

1995; Farquhar et al., 1990; Luepker et al., 1994). Each trial succeeded in developing and implementing its community-based intervention on a broad scale, involving large numbers of programs and participants. Furthermore, each trial reported strong favorable trends in a broad set of CVD risk factors among individuals in the intervention as well as control cities. However, in spite of the extensive programs implemented in the intervention cities, net improvement of risk factors in intervention over control cities was modest, generally of limited duration, and usually not statistically significant. The strongest treatment effects were documented by the SHDPP in the sample of individuals who were followed longitudinally, where the improvements in the intervention cities were significantly greater than those in the control cities for health knowledge, blood pressure, and smoking, but not for plasma cholesterol or obesity. No significant net improvement of risk factors in intervention over control cities was documented by the MHHP or PHHP. The investigators of the MHHP concluded that their program was unable to generate enough *additional* exposure in a sufficient proportion of the population to exceed the “remarkably favorable secular trends that were ongoing in the study communities” (Luepker et al., 1994).

In a follow-up analysis, the investigators pooled data from the repeated cross-sectional surveys conducted in all three trials (12 cities) to estimate the effect of the intervention with greater sample size than could be attained by a single study (Winkleby et al., 1997). In this larger data set, time trends were estimated for cigarette smoking, systolic and diastolic blood pressure, total cholesterol, body mass index, and estimated 10-year coronary heart disease mortality risk in women and men, 25 to 64 years of age. Results showed that the estimated effects in the intervention cities compared with the control cities were mostly in the expected and favorable direction: 9 out of 12 gender-specific comparisons favored the intervention cities. However, as shown in Table 1, most of the pooled effect estimates were modest in magnitude, and none reached statistical significance at the level of  $p < 0.05$ . The last two columns of the table show the net change and  $p$ -values for the primary hypothesis of an overall net intervention effect (intervention minus control). For example, smoking in the combined analysis declined by approximately 1% per year for both women and men in intervention and control cities. The decline was steeper in intervention cities

by an estimated 0.3% per year for both women and men, but the differences were not statistically significant ( $p$  values 0.48 and 0.54 respectively). For the majority of the remaining risk factors, the time trend was slightly but not significantly steeper in intervention cities than in control cities.

The results from these three CVD prevention trials have been the topic of much debate among health professionals, with many concluding that the large community-based intervention trials of the 1970s and 1980s “failed.” This interpretation is simplistic in that it does not consider the numerous methodological and analytic challenges that such studies face (Atienza & King, 2002; Winkleby, 1994). For example, Mittelman and coauthors (1993) provided a perspective on these studies and pointed out that the limitations of this type of community-based outcomes research include “a plethora of problems,” such as small numbers of analysis units, sampling difficulties, and most important, strong secular trends in control cities—all of which compromise the ability of even the best-endowed studies to detect statistically significant intervention effects. Contributing to the secular trends during the 1970s and 1980s was the acceleration of health promotion via the popular press; the increased health promotion activities by voluntary health agencies such as the American Heart Association and the American Cancer Society; and the advent of broad-based federal programs, such as the National High Blood Pressure Education Program, the National Cholesterol Education Program, and the American Cancer Society’s Great American Smokeout.

One explanation for the poorer-than-expected outcomes of the community trials is that although these interventions were applied on a communitywide basis, they did not focus on populationwide prevention strategies that address social factors that influence the distribution of risk factors (Link & Phelan, 1995). Rather, their main focus was on providing health resources to a large number of individuals in communities where the responsibility for maintaining and improving health was with the individual. The rationale for this approach is that once individuals are informed of their risk, they will adopt or modify behaviors to lower that risk. The emphasis is on providing individuals with information, knowledge, or skills so they can avoid or modify high-risk behaviors. While an individual approach can be effective for addressing health problems (especially at the secondary

**Table 1** Cardiovascular Risk Factor Trends in Women and Men aged 25 to 64, Joint Analysis of Three U.S. Community-Based Intervention Trials for Cardiovascular Risk Reduction, 1978-1990, Combined Trends, Adjusted for Age and Education<sup>a</sup>

<sup>c</sup> Test for presence of net intervention effect (i.e., difference between combined intervention and control trends).

and tertiary prevention levels), it often has had limited success because it (a) places the burden for change on individuals who are often those with the fewest resources, (b) deflects attention away from important factors in the social and physical environment that influence choices regarding health-related behaviors, and (c) does not provide reinforcement of positive health behaviors from the environment in which an individual lives and works.

In addition to the strong secular trends in control cities, there are other issues that complicate the interpretation of the three CVD prevention trials. Some of these issues relate to the composition of the communities themselves. For example, just as some individuals have better resources for changing health behavior,

it is plausible that some neighborhoods within the intervention cities had better resources to support positive behavior change than other neighborhoods, resulting in greater change among the individuals living within the higher resource neighborhoods. This differential change would be masked by overall results that combined all neighborhoods within an intervention city. The possibility of this effect is supported by previous studies that have shown that the onset of the decline in CVD occurred earlier in areas with greater resources (Wing, Barnett, Casper, & Tyroler, 1992).

What, then, is the future of community-based CVD prevention efforts? The rationale for the community approach to CVD control is evident; it includes a high

degree of generalizability, cost effectiveness in using mass communication methods, diffusion of information through increased discussion about health, and ability to influence environmental, regulatory, and institutional policies that enhance health. Also evident is the need for programs and strategies that encourage people to stop smoking, undergo blood pressure screening and treatment, exercise regularly, decrease overconsumption of food, and increase consumption of vegetables and fruits. Recent CVD prevention and control programs are combining individual with populationwide strategies that involve collaborative community involvement and infrastructure development that address environmental and policy change (Israel et al., 1998). This combination of strategies appears promising. For example, the Child and Adolescent Trial for Cardiovascular Health (CATCH) demonstrated that changes in policies and practices of schools can positively affect health behaviors. CATCH included 56 intervention and 40 control schools and used a 3-year intervention that modified the fat content of school lunches and increased the intensity of activity in physical education classes. Intervention schools showed significantly greater reductions in energy intake from fat and greater increases in intensity of physical activity compared with control schools following the intervention (Luepker et al., 1996).

The most recent studies are broadening the concept of the population approach to prevention by examining how the social and physical milieu of communities may affect individual health behaviors and CVD (Diez Roux et al., 2001). These studies are also broadening the concept of evaluation to include not only physiological endpoints but also qualitative parameters at the individual, organizational, and policy levels that may influence health. The underlying premise of these studies is that an individual's ability to adopt and maintain healthy behaviors is influenced by goods and services in his or her community as well as policies and regulations at both the local and national levels. This premise is supported by the theoretical literature that proposes that personal, cultural, and environmental factors interact to determine an individual's health behaviors. This new, broader approach to the prevention of CVD will allow investigators to examine underlying determinants of CVD, with the hope that all people, including those in population subgroups that bear a disproportionate burden of cardiovascular morbidity and mortality, will have the

opportunity and resources for enhanced cardiovascular health.

## CARDIOVASCULAR PSYCHOPHYSIOLOGY: MEASURES

---

The existence of physiological concomitants of emotional stress has long been recognized, but only relatively recently have they been the subject of systematic scientific inquiry. Historically, Walter B. Cannon's 1915 landmark text, *Bodily Changes in Pain, Hunger, Fear and Rage*, set the stage for the field of cardiovascular psychophysiology, which has emerged with the objective of documenting cardiovascular correlates of behavior, with particular emphasis on the effects of stress. A guiding research hypothesis has been that psychological stress may contribute to the development of cardiovascular disease and also to the occurrence of acute clinical events such as heart attack in patients rendered susceptible by preexisting disease. Therefore, considerable effort has been devoted to characterizing responses of the cardiovascular system elicited by stress in order to illuminate the physiological mechanisms whereby stress may be implicated in cardiovascular pathophysiology.

### LABORATORY STUDIES

For the past 50 years, research on the effects of stress on blood pressure (BP) has been dominated by "cardiovascular reactivity" studies, in which a variety of cardiovascular measures are recorded while human volunteers are subjected to psychologically stressful tasks in a research laboratory setting. Responses to a wide variety of stressors have been documented, including reaction time tasks, mental arithmetic, simulated public speaking, cold pressor tasks, and a variety of psychomotor tasks. One important feature of cardiovascular responses to these laboratory-based stressors is that individual differences are strikingly varied. For example, while some individuals may show an increase in heart rate (HR) of 50 beats per

minute (bpm) during a mental arithmetic task, others may exhibit only 1 or 2 bpm change in HR. Moreover, individual differences in cardiovascular reactivity appear to be relatively stable traits, exhibiting consistency across stressors and stability over time. Here we briefly describe a number of physiological measures commonly used in cardiovascular psychophysiology research.

### Heart Rate

Heart rate, expressed in bpm, is perhaps the most widely used measure in cardiovascular psychophysiology. HR is usually quantified from the electrocardiogram (EKG), based on the time-interval between successive R-waves in the EKG complex. The EKG R-R interval, or interbeat-interval (IBI), measured in milliseconds, is favored by many physiologists because it is considered to be the critical parameter regulated by the autonomic nervous system. HR is more familiar because it is readily accessible by counting the pulse, and shows a reciprocal relationship with IBI, as shown by the formula  $HR \text{ (bpm)} = (60)/(IBI \times 1000)$ .

### Blood Pressure

The most commonly measured characteristics of arterial BP are the maximum and minimum pressures with each heartbeat, referred to as systolic blood pressure (SBP) and diastolic blood pressure (DBP) respectively. The emphasis on these parameters, both in medicine and in psychophysiology research, is partly a reflection of their relative ease of measurement using noninvasive techniques. SBP and DBP are most commonly assessed in the arm's brachial artery, using either the auscultatory or oscillometric measurement technique. Both techniques employ an occlusion cuff that is inflated to first interrupt and then progressively restore blood flow through the brachial artery. With the auscultatory method, a microphone or stethoscope is then used to detect Korotkoff sounds (caused by turbulent blood flow in the brachial artery) as the cuff slowly deflates. SBP is recorded as the cuff pressure in mm Hg corresponding to the first detection (Phase I) of Korotkoff sounds, and DBP is the pressure corresponding to the muffling (Phase IV) or disappearance (Phase V) of Korotkoff sounds. Mean arterial pressure (MAP) is then estimated using the formula  $MAP = DBP + (SBP - DBP)/3$ . With oscillometric BP

measurement, pulsatile pressure oscillations that are transmitted from the brachial artery to the occlusion cuff provide the basis for BP assessment. When the cuff slowly deflates through SBP, pulsatile pressure oscillations that arise in the cuff mark SBP; subsequently, the maximum amplitude of cuff pressure oscillations indicate MAP; when cuff pressure oscillations become markedly attenuated, DBP is indicated. SBP and DBP are measured in millimeters of mercury (mm Hg).

In addition to these traditional methods, there are newer techniques for assessing BP on a beat-by-beat basis that have become widely used in cardiovascular psychophysiology. The most accurate and direct is intraarterial recording of the arterial pulse pressure waveform, which is invasive and not without risk. However, there are noninvasive beat-by-beat assessment techniques that have become widely accessible with the commercial packaging of the advanced technology on which they depend. Arterial tonometry is a technique that involves the application of a pressure transducer to skin that is directly over an artery (e.g., the radial artery in the wrist). A small amount of pressure is applied to the transducer, and pressure changes in the artery are transmitted through the tissues to the skin, where they are measured precisely. The arterial BP waveform is calibrated against values from a BP cuff at another site (e.g., brachial artery at heart level). There is also the "vascular unloading" technique that involves inflating a small BP cuff positioned around a finger. With this technique, blood volume in the artery under the cuff is detected with a photoplethysmographic sensor (i.e., light sensor), and this information is used to keep volume constant by almost instantaneous adjustments in cuff pressure; with this approach, cuff pressure mirrors arterial pressure in the finger. Assessment of beat-to-beat BP is of considerable interest because it makes possible an assessment of rapid changes in BP, whereas the more traditional upper arm occlusion techniques are limited to BP measurements of about once per minute. It is important to note, however, that BP does not remain constant throughout the arterial system, with pulse pressure widening as arteries become more peripheral. Thus, SBP is typically higher in the finger than the arm, and DBP typically lower. Moreover, BP responses to stress are often greater in the finger than the arm, emphasizing the importance of ascertaining the BP measurement technique employed when comparing findings from psychophysiological studies.

### Cardiac Output and Systemic Vascular Resistance

When cardiac output (CO), the volume of blood pumped by the heart per minute, is measured simultaneously with BP, it is possible to gain a more complete hemodynamic assessment of circulatory responses by also deriving total peripheral resistance (TPR) of the vascular system. TPR is computed by dividing MAP by CO; as implied by this equation, changes in BP are the direct result of changes in either CO and/or TPR. Thus, a BP increase during stress may, for example, be characteristic of the fight-or-flight response (increased CO and decreased TPR), or a net peripheral vasoconstriction response (increased TPR), or a simultaneous increase in both CO and systemic vascular resistance (SVR). Cardiovascular psychophysiology research over the last 20 years has established that there are marked individual differences in hemodynamic response patterns during stress; that such individual differences appear to be relatively stable psychophysiological traits; and that these response patterns may be related to cardiovascular disease risk.

Most behavioral research studies that have included CO assessment have used impedance cardiography, a noninvasive, unobtrusive and continuous measurement technique that is ideally suited for monitoring cardiovascular responses during psychological stress. Impedance cardiography involves the application of four disposable band-electrodes around the neck and chest, together with a standard EKG. Because the impedance cardiogram is susceptible to respiratory and movement artifact, computer ensemble averaging is typically employed to enhance measurement reliability.

### Limb Blood Flow

The measurement of forearm blood flow is one of the longest established cardiovascular psychophysiology measurements. Blood flow to the forearm is of interest because it is considered to provide an indication of blood flow responses to the skeletal muscles, which should increase during stress if the fight-or-flight response is elicited. Venous occlusion plethysmography is the technique most widely used to assess forearm blood flow. This technique involves placement of a two occlusion cuffs around the arm, one just above the crease of the elbow, and one around the wrist. The upper arm cuff is inflated to a pressure above venous BP but below DBP (e.g., 40 mm Hg) for

a few seconds, and then deflated for several seconds; during inflation, blood flows freely into the forearm but cannot escape. The wrist cuff is inflated to a suprasystolic pressure (e.g., 200 mm Hg) to obviate measurement of blood flow into the hand. A volumetric transducer, typically a mercury-in-Silastic strain gauge, is used to quantify the rate of increase in forearm volume, which is attributed to the inflow of blood in milliliters per minute (ml/min).

### Autonomic Nervous System

Cardiovascular responses to stress often involve both branches of the autonomic nervous system, and there are a variety of measures of autonomic activity that are more or less specific to the sympathetic (SNS) and parasympathetic (PSNS) nervous systems. For example, HR is regulated by both the SNS and PSNS, increasing with heightened sympathetic outflow to the heart and decreasing with heightened parasympathetic activity.

Commonly used indices of SNS activity include measures of cardiac contractility and catecholamine levels in the blood and/or urine. Preejection period (PEP) is a systolic time interval, referring to the portion of the cardiac cycle during which the left ventricle contracts isovolumetrically, prior to the ejection of blood into the aorta. PEP shortens with increased SNS influences on the heart and is therefore inversely related to SNS activity. However, PEP is an imprecise measure of SNS activity because it is affected by other factors, most notably cardiac preload and afterload. The Heather Index is a related index of cardiac contractility that is unique to impedance cardiography. It is derived by dividing peak left ventricular ejection velocity by the time required for its achievement during cardiac systole. Both PEP and the Heather Index may be measured noninvasively.

Catecholamine levels in the blood show robust responses to stress. Plasma norepinephrine (NE) and epinephrine (EPI) are the two most commonly measured catecholamines. NE is the postsynaptic neurotransmitter used by the SNS, whereas EPI is released by the SNS into the circulation from the adrenal medulla and thereby acts like a hormone by reaching target receptors in the heart and vasculature through the circulation. The half-life of catecholamines in the blood is very brief, and therefore timing of blood sampling intended for catecholamine analysis is a critical consideration. Ideally, blood should be sampled using

a continuous withdrawal pump, and immediately stored on ice, in order to provide plasma catecholamine samples that will be most representative of responses to acute laboratory challenges. Using either high-performance liquid chromatography (HPLC) or radioimmunoassay (RIA), both NE and EPI can be assayed from arterial or venous blood samples, as well as from urine samples.

NE and EPI exert their effects on the circulation via adrenergic receptors in the heart and vasculature. To better understand how the SNS mediates the cardiovascular effects of stress, psychophysiological research has also included the evaluation of cardiovascular alpha- and beta-adrenergic receptors. Available techniques include the *in vivo* response of the heart and vessels to the intravenous infusion of selective adrenergic receptor agonists (e.g., isoproterenol and phenylephrine), and *in vitro* techniques that quantify the density and sensitivity of adrenergic receptors on tissue samples (e.g., blood lymphocytes and platelets).

Two widely used measures of parasympathetic nervous system activity are high frequency heart rate variability (HF-HRV) and baroreceptor sensitivity (BRS). HF-HRV is commonly termed respiratory sinus arrhythmia (RSA) because HF occurs at respiratory frequencies (i.e., 0.15-0.40 Hz), with HR typically increasing during inspiration and slowing with expiration. Multiple mechanisms contribute to HF-HRV, and therefore it does not reliably measure the absolute level of vagal input to the heart in every measurement context, and HF-HRV is best used to assess changes in parasympathetic cardiac control. In addition, HF-HRV values are related to the rate and volume of respiration, so accounting for respiration is important for optimal interpretation of HF-HRV. Several techniques have been employed to quantify HF-HRV, but all essentially involve accurate measurement of the cardiac interbeat interval (IBI) in milliseconds, so that the variations occurring in the respiratory frequency can be quantified and expressed in  $\text{ms}^2/\text{hz}$  or  $\ln(\text{ms}^2)$ .

Baroreceptor sensitivity (BRS) is a measure of the functioning of a reflex loop involving pressure-sensing nerves (i.e., baroreceptors) in the carotid arteries and the aorta. Changes in arterial pressure stimulate the baroreceptors, and HR is increased or reduced via the vagus nerve as a buffering mechanism to maintain appropriate BP. The arterial baroreceptors also maintain a tonic level of vagal activity in the absence of

rapid arterial pressure changes, so the contribution of arterial baroreflexes to parasympathetic tone is substantial, although other mechanisms such as central vagal drive are also involved. There are several methods for measuring BRS. Invasive methods involve the use of vasoactive drugs to induce changes in arterial BPs or mechanical suction applied to the neck to activate or deactivate the carotid artery baroreceptors. Changes in heart period resulting from changes in arterial pressures are then used to assess BRS. Noninvasive methods of measuring BRS involve the analysis of continuously recorded SBP and IBI to reveal spontaneous BRS, typically expressed in  $\text{ms}/\text{mmHg}$ .

## ULTRASOUND IMAGING

The use of ultrasound imaging techniques has gained popularity in cardiovascular psychophysiology as an approach to evaluating both causes and consequences of cardiovascular responses to stress. Echocardiography is perhaps the most widely used approach to assessing “target organ damage” in terms of cardiac structure and functional pathology such as left ventricular hypertrophy (LVH), or enlargement of the heart. Vascular imaging techniques also have been used to evaluate vascular damage, as indexed by the presence of arterial (e.g., carotid) plaques and measures of arterial intima-media thickness (IMT). Vascular ultrasound measurement of flow-mediated dilation (FMD) of the brachial artery also has been employed to assess vascular endothelial function. Recent FMD studies in cardiovascular psychophysiology suggest that endothelial function may both alter and be altered by the stress response.

## AMBULATORY MONITORING STUDIES

### Ambulatory Blood Pressure Monitoring

Technological advances in BP monitoring equipment have made the assessment of ambulatory blood pressure (ABP) widely available. ABP monitors are wearable and relatively unobtrusive devices, typically using auscultatory or oscillometric methods to noninvasively measure ABP during typical daily activities and during nighttime sleep. Assessment of ABP often takes the form of a 24-hour ABP record with defined measurement intervals (e.g., every 15 minutes during the day and every 30 minutes during nighttime sleep). During waking hours, psychophysiological ABP

assessments usually also require subjects to complete a small paper or electronic diary following each waking ABP measurement. The diary is used to collect information about the time of the ABP reading and recent ingestion of substances that may affect BP (e.g., tobacco, caffeine), as well as the person's posture, physical activity, location, and mood or psychological state (e.g., perceived stress level). ABP studies have demonstrated that real-life stress is associated with higher ABP in association with chronic real-life stress (e.g., job strain), and also that the occurrence of more brief episodes of stress is associated with acute rises in ABP. Diurnal ABP patterns are also of interest, with recent evidence that "nondipping," or failure to exhibit the typical drop in BP during the nighttime sleep period, is associated with heightened cardiovascular risk and target organ damage.

### Ambulatory Hemodynamics

Several ambulatory impedance cardiography monitors have become available to researchers in the last few years. These monitors are similar in size to ABP monitors and provide a means of 24-hour monitoring of cardiac performance, including cardiac output. When worn and configured to take measurements simultaneously with ABP monitors, they provide a combined capability of 24-hour hemodynamic monitoring.

### Heart Rate Variability

Measures of HRV derived from 24-hour EKG recordings have been used for many years to assess autonomic functioning. Interest in ambulatory assessment of HRV derives in part from the fact that 24-hour HRV is an independent predictor of risk of mortality following MI and because depressed cardiac patients have been observed to have lower HRV than non-depressed patients. A number of time domain and frequency domain methods can be used to quantify the variation in HR or R-R interval. For example, a very widely used time domain measure is the standard deviation of all normal R-R intervals (SDNN). When frequency domain measures are used, the high frequency component (HF-HRV) is often interpreted to reflect parasympathetic cardiac control. However, the same interpretative caveats discussed for laboratory measures of HF-HRV apply to longer collection periods (e.g., the need to control for the influences of respiration). In fact, the autonomic origins of various

measures derived from 24-hour HRV measures can be difficult to interpret because of the contribution of nonautonomic factors to variation in HR (e.g., hormones, activity, posture).

### Catecholamines

A few studies have assessed SNS activity according to plasma catecholamine levels in an ambulatory setting by using wearable blood withdrawal and collection systems. However, more commonly, the collection and cold storage of urine by study participants has been used to provide an index of overall SNS activity over periods from hours to days. Urinary NE and EPI excretion rates should be adjusted for individual differences in body size, for example, by expressing excretion rates relative to creatinine excretion (a byproduct of muscle metabolism). In contrast to plasma catecholamines, NE may be a more meaningful SNS index as measured by urinary excretion, whereas urinary EPI levels may be confounded by EPI originating in the kidneys (especially in patients with hypertension).

### SUMMARY AND FUTURE DIRECTIONS

This entry has summarized some of the measurement techniques employed in the field of cardiovascular psychophysiology. Using these techniques, the cardiovascular response to psychologically demanding tasks has been documented comprehensively in the laboratory setting, and there is compelling evidence to suggest that the stress response may be a cardiovascular risk factor for some individuals. In recent years, cardiovascular psychophysiology research in the "real world" has been made possible by the development and refinement of ambulatory measurement techniques. Ambulatory cardiovascular psychophysiology appears likely to play a more prominent role in the future, where it promises both to confirm and extend our understanding of cardiovascular-behavioral interactions and the relationship of stress to cardiovascular risk.

## CARDIOVASCULAR REACTIVITY

---

Cardiovascular reactivity (CVR) has been defined by Stephen B. Manuck, a seminal theorist in this area, as “an individual’s propensity to experience cardiovascular reactions of greater or lesser magnitude, in relation to those of other persons, when encountering behavioral stimuli experienced as engaging, challenging, or aversive” (Manuck, 1994).

Several studies indicate that behavioral and psychosocial factors such as anger, hostility, Type A personality, lack of social support, and exposure to stress are linked to hypertension (HTN) and/or coronary heart disease (CHD). The pathways by which these factors promote disease remain controversial. A predominant psychophysiological theory invokes a model in which CVR acts as the primary marker or pathway. The reactivity hypothesis originally stated that persons classified as “hyperreactors” (those exhibiting large cardiovascular responses) to stressful stimuli may be at increased risk of developing HTN (the “weak” form of the hypothesis). In its stronger form, the hypothesis states that such hyperreactivity plays a causal role in the sustained elevation of resting blood pressure (BP)

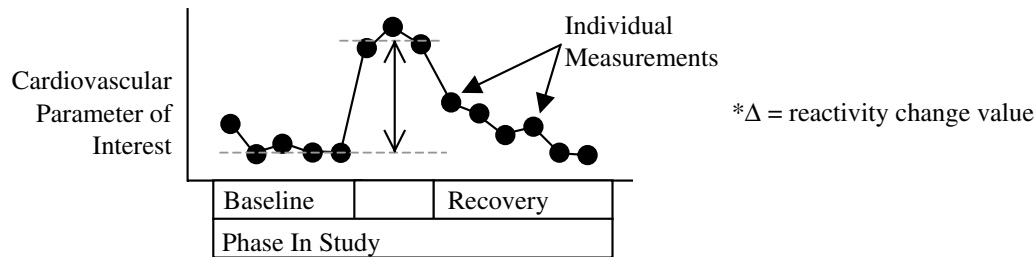

and development of HTN. More recently, reactivity has been postulated to also play a role in the development of CHD.

## STRESS

The physiologist W. B. Cannon first used the term *stress* in a nonengineering context to refer to the influences of the environment on psychological processes that in turn were related to physiological outcomes (see Stress, Appraisal, and Coping in this volume). The idea was further developed by R. S. Lazarus and his colleagues, who suggested that a person must perceive a situation as “stressful” before a physiological stress response will occur. This notion holds important implications for current research in stress. Rick Turner, in his excellent book on CVR and stress (Turner, 1994), points out that the purpose of fight-or-flight responses, as Cannon described them, is to prepare the organism for immediate physical action. Increased cardiovascular activation, as well as neurohormonal activity such as the release of cortisol, act to facilitate the additional nutritional supply needed for such physical activity and the preparation to minimize damage due to physical threat. Turner notes that in a highly evolved social society, the threats may be symbolic, such as may occur in an unpleasant social interaction, rather than physical; however, it appears that these challenges may evoke physiological adjustments that are similar to those seen in response to a physical threat. There are two important implications to this, Turner suggests: (1) moderate levels of cardiovascular and neurohormonal arousal may be repeatedly elicited during everyday life, and (2) these responses may be modeled in the laboratory using psychological challenges.

## ORIGINS OF THE CARDIOVASCULAR REACTIVITY MODEL

In the 1930s, E. A. Hines and G. E. Brown sought a means by which physicians might identify persons at future risk for high BP (Hines & Brown, 1936). The rationale was clearly stated by Ayman and Goldshine (1938): “[M]any young people are certain to develop essential HTN some day. If it were possible to apply a standard stimulus to such persons, it might be possible to determine a group in which an abnormally great reaction resulted from this stimulus. In other words, it might be possible to determine in advance the future subjects of essential HTN.”

**Figure 1** Schematic Representation of a Cardiovascular Reactivity Study

To this end, Hines and Brown conducted a study that was to become a model for CVR testing: normotensives and hypertensives first sat quietly while BP measurements were taken to provide a resting, or baseline level, and then were exposed to a cold stimulus (the “cold pressor test”), in which the hand was immersed in ice water. The measure of reactivity was the difference in BP between the prestress baseline and stressor levels. They found that, compared to normotensives, hypertensive patients exhibited greater BP reactivity in response to the cold stimulus; in addition, they found that the BP of the normotensives tended to return to the prestress level more quickly. These results have been replicated in several subsequent studies.

### The Study of Cardiovascular Reactivity in the Laboratory

Certain features are common to most CVR studies, and have remained remarkably consistent across studies and over time. Figure 1 shows a schematic of a typical reactivity study.

1. Subjects are instrumented with a device that measures cardiovascular variables (usually BP and/or heart rate).
2. Subjects sit quietly during a baseline period (a), usually between 5 and 30 minutes. The purpose of this phase is to provide a within-person comparison against which the effect of the stressor may be assessed.
3. A stressor is then presented (b). The duration is usually 2 to 5 minutes, although longer tasks have been used. The mean of the cardiovascular measurements is generally computed, although peak response is sometimes used.
4. A change score is usually computed, in which the baseline measure is subtracted from the stressor level ( $\Delta$ ). Some researchers statistically control for the effect of the baseline level, to account for individual differences in resting levels.

5. In some studies, recovery from stress is assessed during a posttask rest period (c).

### A Trait Conceptualization of Cardiovascular Reactivity

Following Hines and Brown, for almost two decades reactivity studies used the cold pressor as the stressful stimulus. An important assumption implicit in these studies was that the particular eliciting stimulus didn't matter, as long as the *same* stimulus was used across subjects. This underscores the view, held early on, that CVR was a generalized trait, that is, some people are simply more reactive than others, regardless of the stimulus, and these persons are at greater risk for developing HTN.

### Cardiovascular Responses to Mental or Emotional Stressors

The first use of a “mental” task, a stressful interview, occurred in the 1950s. Later, mental arithmetic was used and soon became (and remains) the most commonly used mental stressor in reactivity testing, although many other tasks, such as the Stroop color-word matching task, public speaking, and star-mirror tracing, have been used.

If indeed the choice of the stimulus is arbitrary, then cardiovascular responses to one stressor should predict those to any number of others. In the 1970s, studies evaluating this premise were performed, and it became clear that a great deal of inconsistency between responses to different stressors existed, with intertask correlations in the range of 0.40 to 0.50. This led to important advances in the conceptualization of the reactivity model in that researchers became concerned with the meaning and selection of the eliciting stimulus.

### Stability of Cardiovascular Reactivity Within Persons Over Time

A crucial aspect of any trait concerns its stability over time, usually assessed as “test-retest reliability.” Manuck (1994) reported that test-retest coefficients for systolic and blood pressure change averaged only 0.51 and 0.34, respectively. In recent studies, Thomas Kamarck and his colleagues found that, as might be expected from classical measurement theory, aggregating measurements to several stimuli improved the test-retest reliability (Kamarck, Jennings, Debski, Glickman-Weiss, & Johnson, 1992). These results suggest that the CVR *construct* is fairly stable over time, but that the observed reliabilities have been limited by the single-stimulus methodology commonly employed.

### Do Cardiovascular Stress Responses Generalize to the Natural Environment?

In a *risk marker* model, reactivity observed in the laboratory is thought to be associated with the development of disease, but is not necessarily thought to play a causal role. However, in a model in which reactivity is considered to be a *cause* of disease (i.e., the “strong” version of the reactivity hypothesis), responses measured in the laboratory will allow prediction of disease development only to the extent that laboratory reactivity is a good analogue of cardiovascular adjustments that occur in the natural environment. Thus, several studies have examined the laboratory-to-life generalizability of laboratory-based CVR measurements. For the most part, these studies have yielded weak results. Several studies show a failure of laboratory reactivity to generalize to real-world situations. Others indicate small to moderate generalizability of some measures or some reactivity tasks.

Reactivity is exquisitely vulnerable to situational effects. Thus, there may be no “true” reactivity that can be captured in the laboratory. Situational effects and person-by-situation interactions place limits on the potential for generalizability, as laboratory-life comparisons are inherently cross-situational. However, even studies in which exposures are uniform show that laboratory reactivity poorly predicts cardiovascular responses in the natural environment. A distinction must be drawn, however, between the cardiovascular reactivity *construct* and the laboratory *method*; thus, it remains entirely possible that frequent BP and/or heart rate elevations in response to stress are a factor in the

development of HTN and/or CHD, and that our failure to observe laboratory-to-life generalizability represents only a limitation of laboratory measurements.

### Prospective Studies of Cardiovascular Reactivity and the Prediction of Hypertension

A handful of prospective studies have been conducted in which reactivity testing has been performed in normotensives who were then followed to determine which subjects became hypertensive and which did not (it was later that outcome measures other than HTN became a focus of the reactivity model).

Four of the earlier studies (all using the cold pressor) did not find that reactivity predicted the future development of hypertension. One study claimed positive results, but of the 207 subjects followed over a period of 27 years, only 4 subjects became hypertensive, 3 of whom had a positive family history of hypertension. More recently, two studies have shown positive results. In one, normotensives who exhibited greater blood pressure reactivity to the cold pressor tended to be at greater risk for developing HTN during a follow-up period of 45 years. A second study showed similar results, with the effect appearing more pronounced in men under age 45 and after controlling for other traditional risk factors. However, a recent study of British civil service employees (the Whitehall Study) failed to find evidence of a prospective association.

Several prospective studies have examined cardiovascular responses of children and adolescents. In a recent comprehensive review, Frank Treiber and his colleagues (Treiber et al., 2002, in press) provide details of several studies that have used a variety of laboratory stressors to predict subsequent BP levels. Treiber notes that the 10 studies reviewed all showed positive results, with children who exhibited larger acute BP responses to mental stress having higher subsequent resting BP levels. Treiber et al. concluded that CVR is a consistent independent predictor of future hypertensive status when long-term follow-ups are conducted.

### Prospective Studies of CVR and the Prediction of Subclinical and Clinical Endpoints

Treiber et al.'s (2003) recent paper provides an excellent review of the prospective studies of subclinical and clinical endpoints; a summary is presented below.

*Prediction of left ventricular mass (LVM).* Only one study to date has examined LVM in adults, which is the strongest predictor of CVD morbidity and mortality other than advancing age; the results showed that CVR to mental arithmetic and an isometric handgrip task accounted for 15% of the variance in LVM change over a 3-year period. A few studies have been conducted in which children were studied, and although some positive results have been found, these were often confounded with other predictors, such as body mass index and height.

*Prediction of carotid atherosclerosis.* At this time, there have been four longitudinal studies of the prediction of carotid atherosclerosis. Treiber et al. report that these studies have tended to be positive, although the pattern of results has been varied and straightforward interpretations of the causal nature of the relationships problematic. In one particularly interesting study, Susan Everson and her colleagues found a significant interaction between systolic BP reactivity and job demands on several measures of carotid atherosclerotic progression, with the high work demands-high reactor group showing the greatest degree of 4-year progression. The pattern of effects was observed even among those men without prevalent ischemic heart disease; however, the strongest effects were observed among the portion of the sample with some evidence of carotid thickening at baseline.

*Prediction of clinical CVD or its progression.* The most significant results would concern the prediction of actual clinical events. In their review, Treiber et al. showed that the results of the six studies that have been published to date again are mixed. Two of the studies showed no relationship, three did show a relationship (although in one the relationship was only with diastolic reactivity, not systolic or heart rate). Moreover, in one of the studies showing a positive outcome, the measure of reactivity used was the difference between BPs taken by a doctor and by a nurse. This "white coat effect," however, may represent a qualitatively different dimension than other mental stressors. In the sixth study, an *inverse* relationship was found, with *lower* heart rate reactivity predicting mortality. The inconsistency among the results highlights the type of problems that continue to plague the reactivity literature. There is little standardization of stressful laboratory tasks, the assessment methods and venues differ and may affect acute cardiovascular responses, and it remains unclear what any particular stressful stimulus may represent for a particular person.

In summary, while there is some evidence that cardiovascular reactivity may predict the development of HTN, of preclinical disease states, and of clinical events and mortality, the data remain sparse and inconsistent, and strong conclusions remain unwarranted.

### The Influence of Paul A. Obrist

Many stressors have been used in CVR studies, but little standardization has occurred and often there is no particular rationale for the use of one stressor or another. However, in the 1970s, Paul A. Obrist, a prominent psychophysiological, made an important contribution in this area.

Obrist suggested that many behavioral stressors involve "active coping," that is, exercising control and effort to cope with stress. In contrast, a passive stressor was one that did not elicit such coping efforts. He hypothesized that situations that provoked active coping produced in some persons reactions of the heart that are unjustified in terms of concurrent levels of metabolic activity. Thus, sizable increases in cardiac activity occur, but in the context of only marginal increases in energy expenditure. Douglas Carroll (Carroll, 1992) has pointed out that this pattern of reaction contrasts to responses to physical exercise, where the amount of the increase in cardiac activity closely mirrors the increase in the physical demands of the exercise. Obrist has suggested that this results in overperfusion, particularly of skeletal muscle tissue. Blood is pumped to these muscles to an extent that is surplus to the muscles' requirements for energy. This in turn precipitates vascular autoregulation, adjustments to the circulation in order to compensate for the overperfusion. These autoregulatory adjustments take the form of increases in arterial resistance.

This sequence of events, it is argued, leads to a sustained increase in BP occurring in response to even transient stressors. BP rises initially as a result of increased cardiac activity; the BP elevation is then maintained by the autoregulatory increase in resistance.

Obrist's research marked a turning point in reactivity models, in part because it suggested that psychological dimensions of the stressor stimulus were important, and provided a distinction between active coping and passive stressors.

Indeed, active and passive coping appear to differ in their hemodynamic effects. Active coping appears to elevate blood pressure via increases in stroke volume and cardiac output. Passive stressors, in contrast, appear to elevate blood pressure by increasing total peripheral resistance. However, neither active nor

passive tasks elicit a clear and simple hemodynamic pattern in all persons. Responses to most stimuli, by most persons, are mixed, with some of the BP elevation due to increased cardiac output and some due to increased resistance. Thus, it is premature at this time to draw strong conclusions; however, the results to date suggest that assessment of these parameters may prove a useful complement to CVR testing.

### **Genetic, Constitutional, Personality, and Situational Effects on CVR**

*Effects of family history of HTN.* A positive family history is a predictor of HTN. Thus, one research strategy has been to see if persons with a family history of HTN tend to exhibit exaggerated CVR to stress. Although some negative findings have been reported, the consensus is that family history of HTN is associated with increased CVR.

*Twin studies.* Several studies have been published that examine the concordance ratios of CVR in monozygotic and dizygotic twins, in children and adults. Overall, there tends to be a stronger relationship between stress reactivity in MZ than in DZ twins, suggesting a stable genetic component. A good example is the NHLBI Twin Study, which has examined twin brothers who were veterans of World War II and the Korean conflict. Reactivity data were obtained from 101 twin pairs; the intraclass correlations of the systolic/diastolic BP changes in response to stress were 0.71/0.56 (MZ) and 0.31/0.23 (DZ). Thus, some proportion of the variance in CVR appears to be attributable to genetic factors.

*Effects of age.* Few studies have examined the effects of age on CVR. For BP reactivity, some studies have shown a positive effect of age, and others have shown no effect. For heart rate reactivity, the results are more consistent: HR responses to stress tend to decline with increasing age.

*Effects of gender.* Men are at greater risk for HTN and CVD during early adulthood and middle age; however, the prevalence of both HTN and CVD increase dramatically in women after menopause, so that among those 75 and older, a greater percentage of women than men have HTN and CVD.

As a result, researchers have examined the effects of gender and of menopause and menstrual cycle in women. The gender comparisons have tended to show

that men exhibit greater systolic BP reactivity to stress, while women tend to have slightly greater HR responses.

*Menopause.* Few studies of premenopausal versus postmenopausal women have been conducted. However, the data that do exist suggest that postmenopausal women tend to have greater HR and systolic BP reactivity than premenopausal women.

*Menstrual cycle.* Several studies have examined this factor, and the results have been inconsistent. Studies employing a between-subjects design have found little or no effect of the phase of menstruation (the luteal or follicular phase) on CVR; studies that have used within-subject designs have tended to show positive results, but the effects have not been large. Katherine Stoney analyzed the results across studies, and suggests that these influences probably do not represent a large influence on CVR (Stoney, 1992). However, she also notes that it is possible that reproductive hormones may play a role in modulating the stress responses in women with abnormal menstrual cycles, and that large changes in hormonal levels may play a role in stress reactivity.

*Effects of race.* Black Americans are at greater risk for the development of HTN and CHD than Whites; however, the cause of this disparity remains unknown. As CVR is postulated to be a mechanism that influences the development of HTN and CHD, several researchers have compared CVR in Blacks and Whites. Some studies have examined Black-White differences to standard laboratory stressors, such as mental arithmetic, and found mixed results, although a preponderance of these studies have shown that both Black children and Black adults exhibit larger cardiovascular responses to these stressors. A handful of studies have used a stressor that involves racial discrimination. The results have been inconclusive, with some studies showing Blacks having greater reactivity to the stressor and other studies showing null results.

These findings highlight the role of generalizability: It is possible that differences in *magnitude* of the responses between Blacks and Whites may not exist; however, it is also possible that differences in the *frequency of occurrence* of reactivity responses may be greater in one population. Thus, the laboratory may provide only limited information regarding the possible pathogenicity of CVR; instead, field methods, such as ambulatory BP monitoring, may be more appropriate for this purpose.

A recent review by Norman B. Anderson points out that recent findings concerning differences in hemodynamic patterns between Blacks and Whites provide an intriguing possible explanation of differences in risk for cardiovascular disease. Some researchers have found that Blacks have a tendency to respond to stressors with elevations in peripheral vascular resistance, compared to Whites, who tend to respond via increased cardiac output, and that this difference may represent a pathway for development of disease. However, this research is in its early stages, and more work must be done before strong conclusions can be drawn.

*The Type A behavior personality (TABP).* The study of CVR was given impetus by evidence linking the TABP (and one of its components, hostility) with exaggerated CVR. This literature has been extensively reviewed (e.g., see the excellent review by B. Kent Houston, 1988); the results are summarized below.

The strongest associations between the TABP and CVR have been observed using the Structured Interview (SI), which is designed to elicit annoyance and impatience. Sex differences in these relationships have been observed. In males, relationships have been observed in the majority of studies in two types of situations: those that involve harassment of the subject, and those in which there exists a moderate incentive to accomplish the assigned task when the task is difficult, but not extremely difficult (a situation that may lead to helplessness).

For women, however, the TABP, assessed using the SI, has not shown the same associations. For middle-class White women, the associations are most likely to occur when using experimental scenarios that involve verbal exchanges; however, this relation has not been observed for women of lower socioeconomic status (SES) or Black women.

The pattern of results when using a self-report Type A measure, the Jenkins Activity Survey (JAS; which correlates poorly with the SI) have been somewhat different. For men, the TABP has been found to be associated with CVR elicited by tasks that require a fast response time and that are difficult but not impossible. Unlike with the SI, CVR in men does not appear to be associated with tasks that involve harassment; this may be due to the fact that there are relatively few anger-related items on the JAS. For women, little association has been observed between the TABP (assessed using the JAS) and CVR.

Karen Matthews, a leading theorist in the interpretation of the TABP, has suggested that the evidence for a relationship between the TABP and CHD incidence is strongest when the SI is used as the assessment tool and when healthy males are the target population. Thus, the relationship between the TABP and CVR may reflect the epidemiological evidence concerning CHD risk.

*Hostility.* The association between TABP, CHD, and atherosclerosis has been mixed, and many theorists now suggest that only some of the characteristics of the TABP are related to heart disease. It now appears that it is the hostility-anger dimension that is most likely to be involved as a component of cardiovascular disease.

Several researchers have focused on the association between hostility, as a personality trait, and CVR. The recent literature suggests that persons who score high on trait hostility tend to exhibit larger cardiovascular responses than low-hostile persons, but only in situations in which this aspect of personality is relevant, such as when the subject is being harassed while working on a stressful task. This is noteworthy because it undermines the idea of reactivity as a generalized trait construct; that is, the trait may influence reactivity only in some situations and not in others. To the extent that CVR is considered a mediator of the stress-HTN/CHD relationship, it is important to consider the degree of exposure. Thus, a hostile person who is not often exposed to situations in which unpleasant social interactions occur will presumably be at no greater risk for development of cardiovascular disease than a nonhostile person.

*Situational determinants of CVR.* In the past two decades, some researchers had begun to take a different approach to the study of CVR. Rather than regarding CVR solely as a function of the person, the role of situational factors, and their interaction with person factors, have also been examined. The increased reactivity in high-hostile persons, but only during unpleasant social interactions, illustrates this. Other situational influences include the nature of the task. As noted earlier, a task that calls for active coping produces a different hemodynamic pattern than a stressor that does not; in addition, several studies have reported differential effects on reactivity due to manipulations of controllability of task outcomes. Researchers have found that the presence of a supportive

person during stress exposure may *attenuate* CVR. These situational manipulations represent an important development in the reactivity model because, unlike the person models, they directly address the issue of frequency of exposure.

### New Developments

For almost a half century after the seminal studies by Hines and Brown, CVR was regarded as the primary pathway by which psychosocial factors affected cardiovascular disease. In the past two decades, however, researchers have grown increasingly sophisticated regarding multiple pathways that may be implicated in this process, including neurohormonal changes, platelet reactivity, and inflammation. Stress may affect all of these physiological processes, which in turn all appear to play a role in the development of heart disease (although the role they may play in the development of HTN is less clear). The understanding of the role of CVR will advance as it is considered in the context of the multiple influences on cardiovascular disease.

Finally, the CVR paradigm itself has been extended in recent years. Although researchers tended to focus on the cardiovascular changes that occur *during* exposure to a stressor, more recent data suggest that the return to the prestress resting level (see Figure 1) may also have a role in predicting cardiovascular disease. It is worth noting that the seminal first reactivity study by Hines and Brown, performed in 1932, anticipated this development; they found that hypertensive patients not only exhibited greater BP responses to the stressor but were also slower to recover.

### Limitations to the Reactivity Hypothesis

There are two major limitations to the reactivity hypothesis as it is commonly proposed. It has been used to explain how chronic or repeated psychosocial stress can lead to HTN and CHD. By definition, this is a complex process with multiple stages, ranging from the nature and frequency of the stressors, how they are perceived, what physiological effects they have, and how the cumulative effect is implicated in the development of cardiovascular disease. CVR to stress is a small part of this chain, and ignores the multiple processes that are involved. The second issue concerns the nature of the relationship between CVR

and cardiovascular disease. The fact that reactivity predicts the development of HTN or carotid atherosclerosis does not by itself mean that it has a causal role, since it is possible that reactivity is a marker for some other process. For example, although reactivity is commonly studied using psychological stressors, there is no evidence that reactivity to *psychological* stress predicts outcome better than the reactivity to a *physical* stimulus such as exposure to cold, standing up, or exercise, all of which have been shown in some studies to be predictive.

There has recently been much interest in endothelial dysfunction (typically measured as a failure of the arteries to dilate in response to ischemia) as a possible causal factor in the development of HTN and heart disease. Indeed, persons who show an exaggerated pressor response to laboratory stressors also show an impaired vasodilator response to ischemia, which may suggest that CVR may be a marker of endothelial dysfunction, and that the latter may be both a cause and a consequence of cardiovascular responses elicited by stress.

### SUMMARY AND CONCLUSIONS

The study of CVR has played an important role in elucidating the role that physiological responses to stress may play in the development of HTN and CHD. It has provided a framework that has evolved since its inception to encompass a broader picture of the multiple processes that are involved in the development of cardiovascular disease. Thus, the models have been broadened to encompass processes such as neurohormonal responses to stress as well as endothelial dysfunction. And other processes, including the role of heart rate variability, platelet reactivity, and inflammation, all of which show changes in response to stress, are being incorporated into the picture of how the body responds to psychological stress and what role these adjustments may play in the development of HTN and CHD.

## CAREGIVING AND STRESS

---

The role of caregiver to older people in this society is well documented, and those receiving care often have both physical and cognitive limitations. It is also

well documented that caregiving is more often stressful than nonstressful. This stress may increase for caregivers in the future, given that over the next several decades the prevalence of cognitive impairment among older people is expected to increase while physical limitations are expected to remain the same. Furthermore, with the projected increase in the aging population of the United States by the year 2050 (those over age 65 will increase to 20.3%), examining the role of caregiving has become a more critical issue. The importance of this issue is even more significant when we examine the projected increase of racial/ethnic minority elders in the future; it is expected that this group of elders will increase at a much higher rate than non-Hispanic White elders over the next 50 years. From 2000 to 2050, projections indicate that the White elderly population will double and the African American elderly population will quadruple. During this same period, the Hispanic elderly population will increase seven times, the Asian/Pacific Islander elderly population will increase six and one half times, and the elderly American Indian population will increase three and one half times their current numbers.

These figures not only denote a growth in the aging population, they also speak to a growing population of potentially dependent elders in the future, who, like those today, will require care. Most often care is provided in the home by close relatives (spouses and children), who often care for older family members with multiple health problems. Although giving care is not necessarily stressful, a large amount of research information clearly shows that most caregivers experience both the physical and emotional stress effects of caregiving. Other findings show that coping with the stress of caregiving can vary, based on factors such as race, gender, and a number of cultural beliefs and values.

## DEFINING STRESS

Stress has been defined as (a) a demand (environmental, social, or internal) that requires individuals to readjust their usual behavior patterns and (b) enduring problems that have the potential for arousing threat and involve the perception of threat to one's well-being. Stress can threaten the ability to cope and/or adjust, and individuals may become overwhelmed. Researchers have found that the stresses of everyday life can exert a cumulative impact on health.

In the general population, women and people of lower socioeconomic status report higher levels of

stress. Among caregivers, those family members and friends who provide, arrange, or oversee services for older adults with functional disabilities or health needs report higher levels of stress and distress than in the general population. These higher levels of stress are found in community-based caregivers as well as caregivers providing care to institutionalized care recipients. However, similar to the general population, caregivers who are women and people with lower socioeconomic status report higher levels of stress.

It is generally accepted that stress is a multidimensional construct. It is negatively associated with the well-being outcomes of life satisfaction and health and positively associated with depression and placement of the care recipient in a long-term care facility. Caregiving variables associated with an increase in stress include the care recipient's level of need, typically measured as limitations in activities of daily living (ADLs) and instrumental activities of daily living (IADLs), time in the caregiving role, and coresiding with the care recipient. Researchers also document that caregiving is more stressful when caring for a cognitively impaired care recipient. While we generally accept that stress is multidimensional, differentiating stress from burden and strain remains a problem.

Providing care to a chronically ill or disabled family member often involves physical tasks such as lifting, dressing, and bathing. Such constant, and often progressively difficult, caregiving tasks can fill a caregiver's available time and make it difficult to fulfill other obligations. The chronic nature of caregiving, along with the time and physical demands, lead many caregivers to appraise caregiving as a burden, or as stressful. Some researchers have proposed that this appraisal of caregiving as stressful is most likely found in U.S. White culture. They further propose that other cultures would be more likely to appraise caregiving as a natural extension of family life, rather than an interruption of the individual life of the caregiver. Other studies have documented that African American caregivers appraised caregiving as less stressful than White caregivers.

## SITUATIONS CREATING STRESS

Appraisals of caregiving as stressful, and the relationship of caregiving to stress, depend on many variables. Other family roles and competing demands are associated with higher levels of stress, as is an increase in financial difficulties. In addition, as the

disability level of the care recipient increases, so do reports of higher levels of stress. Consequently, social support from others in the caregiver's social network, or from a formal network of helpers (e.g., home health workers), can lessen the stress associated with providing care. Religion and/or spirituality are also documented to help reduce the stress associated with caregiving. African American caregivers have reported God as a source of help, and typically score higher than White caregivers on measures of prayer and comfort from religion. Behaviors such as smoking and changes in weight have also been acknowledged as ways individuals cope with stress. Female caregivers typically report higher levels of stress than males, and caregivers who spend more hours providing care, and those with poorer health, rate their stress as higher than their counterparts.

In addition to poorer emotional health outcomes, higher levels of stress are recognized as detrimental to physical health. Stress is associated with higher levels of blood pressure and heart rate, and is implicated in the development of cardiovascular disease. Lower immune system response, as well as impaired endocrine function, have also been associated with increased stress levels, especially among older caregivers.

## COPING WITH THE STRESS EFFECTS OF CAREGIVING

Current findings show that caregivers use a range of coping styles to address the stress of caregiving, and that these styles vary across diverse groups. It has been found that American Indian caregivers were more likely than White caregivers to use stress management strategies, especially the passive forbearance strategy. In addition, African American caregivers reported using more emotion-focused strategies than White caregivers. Research findings show that African American caregivers reported higher levels of avoidance coping and lower levels of approach coping than White caregivers; these levels of coping were associated with greater negative effects (increased depression and decreased life satisfaction). However, others have found no significant differences in the use of different coping strategies between African American and White caregivers.

One researcher reported that quality of social support predicted confrontive coping, appraisals of perceived rewards predicted palliative coping, and appraisals of perceived costs predicted emotive

coping. It was also found that urban African American caregivers used more behavioral coping strategies than rural African American caregivers. As well, urban African American and White caregivers used more cognitive coping strategies than rural African American and White caregivers. Using an existentialist framework, researchers have found that provisional and ultimate meaning (positive psychological resources that may be used for coping) were higher for African American caregivers than for White caregivers, whereas the effects of provisional and ultimate meaning on negative outcomes were the same for African American and White caregivers.

In recent years, researchers have increasingly examined the role of spirituality and religiosity in understanding how caregivers cope with the stresses of caregiving. A number of studies have reported that African American caregivers cope with difficulties of caregiving with prayer, faith in God, and religion. It has been reported that African American caregivers, unlike White caregivers, reported God to be a part of their informal support to the same extent as family, friends, and neighbors. Some researchers have found that 80% of the African American caregivers reported that prayer, faith, and/or religion was their special way of coping, whereas none of the White caregivers offered those answers. It was found that a palliative coping strategy of prayer/divine trust was used more often than any other coping strategy by African American caregivers. In addition, African American caregivers reported higher religiosity than White caregivers, although religiosity influenced perceived caregiver rewards for both groups. Others, though, have found no difference between African American and White caregivers in assessing the use of spirituality and religiosity in coping with the stresses of caregiving.

The use of social support (both informal and formal), which is an explicit form of active coping, is often used by caregivers. Similar to other coping strategies, different groups may differ in their use of social support. Some researchers report that White caregivers use formal social support as a way of coping with caregiving more than African American caregivers. Conversely, no difference was found in the formal support between African American and White caregivers. Some researchers have found no difference between African American and White caregivers' use of, or satisfaction with, informal support as a way of coping with the demands of caregiving, but they found that White caregivers were more likely

than African American caregivers to report seeking guidance and support as a form of behavioral coping.

## THE ROLE OF APPRAISAL IN COPING WITH STRESS

How one appraises a situation can influence the ability to cope with a stressful situation and the style of coping that may be used. Findings show that African American caregivers tend to use more positive appraisal than White caregivers when dealing with the difficulty of caring for a dependent elder. It was also found that positive appraisal was effective in reducing stress for African American caregivers, but not for White caregivers. Additional research found that caregivers' appraisals and other coping responses mediated the effects of race on well-being. Their findings also show that African American caregivers appraised self-care problems, as well as memory and behavior problems, as less stressful than did White caregivers. However, it was found that African American and White caregivers were similar on indices of appraisal. Finally, findings show that older African American caregivers with lower education were more likely to appraise caregiving as rewarding.

## SUMMARY

We propose that an important next step for researchers and practitioners is to more carefully examine the diverse worlds of caregivers to identify and examine stress effects of caregiving. Furthermore, much more information is needed to help design and implement culturally competent interventions to help caregivers cope with the stresses of their role. For some groups, stress effect interventions may be more related to cultural rather than socioeconomic issues; for others, stress effects may relate to gender issues, or it may be a combination of factors. Findings in the literature point to potential cultural factors that may affect whether one views caregiving as stressful or not. The appraisal of the situation can thus affect whether the situation is perceived as stressful or not. Therefore, more attention is needed when designing interventions for caregivers regarding the mechanisms and pathways through which culture shapes appraisals of the caregiving experience.

## CENTER FOR THE ADVANCEMENT OF HEALTH

---

The Center for the Advancement of Health ([www.cfah.org](http://www.cfah.org)) works to ensure that knowledge about where we live, how we are educated, and what we eat, drink, breathe, and do is used to improve health. As such, the Center is a facilitator and advocate for linking research policy and practice. It does its work by

- Synthesizing research findings and their implications for practice, policy, and future research
- Mapping the dynamics of the issue and determining the following: Who is accountable for solving a specific health problem? What information would help them do so more effectively? How do they currently use science and what are the barriers to using it?
- Facilitating long-term working relationships between scientists and stakeholders to ensure better alignment of science with practice interests
- Communicating research findings to key target audiences, including professional groups, voluntary organizations, Congress, and the public
- Convening leaders to take collaborative action in support of efforts to translate health research into policy and practice

## AN EXPANDED VIEW OF HEALTH

The Center was founded and funded by the John D. and Catherine T. MacArthur Foundation. It is independent and is not aligned with disciplinary, professional, or partisan positions. It has broad subject matter expertise in the behavioral and social sciences and health. The Center maintains long-standing relationships with professional and research societies, science and policy leaders, academic institutions, health nonprofits, foundations, and state and federal government. Its reputation as a neutral convener and a fair and trustworthy partner allows disparate factions to find ways to work together.

The Center, through 10 years of careful investigation and analysis, has explored how and why behavioral and social science on health is underreported and underused in personal, professional and policy decisions. It has drawn attention to the value of using this knowledge in developing effective interventions to improve health and quality of life. And it has contributed to achieving such improvements by working

with the news media, HMOs, insurers, companies, and governments to apply this evidence to the development of their policies, to health care delivery practices, and to the everyday health choices of individuals.

## HEALTH BEHAVIOR NEWS SERVICE

One strategy the Center uses to bridge the gap between research and public knowledge about health is the Health Behavior News Service (HBNS), the aim of which is to focus media attention on behavioral and social determinants of health by promoting scientific developments as news.

The need for the news service came out of the recognition that the heavily funded promotion of biomedical and pharmaceutical science leads to an unintended bias in the news media toward reporting predominantly on biological aspects of health as opposed to balanced reporting that includes the economic, social, and behavioral components of health. This, in turn, presents a dangerously inaccurate picture of what produces disease, and it contributes to a narrow focus on high-tech, expensive fixes with questionable impact.

Science and communications experts at HBNS cull the best new research from more than 30 behavioral and social science journals and translate articles into clear and concise news stories, which are then distributed electronically on an embargoed basis to health reporters. Among the topics HBNS reports on are addictions, adherence to medical advice, aging, cardiovascular health, chronic illness, depression, diabetes, diet, exercise, HIV/AIDS, social determinants of health disparities, and stress.

The news stories are routinely picked up by the Associated Press, Reuters, UPI, and by major publications, including the *New York Times*, *USA Today*, *Los Angeles Times*, *Washington Post*, *Chicago Tribune*, and *Parade* magazine. Journalists and the public may access these stories and briefings from the HBNS's Web site ([www.hbns.org](http://www.hbns.org)). The HBNS also publishes and distributes by e-mail a daily digest of health and behavior articles appearing in the nation's major news media.

The stories inform not only the news media and the general public but doctors and policymakers as well. Unfortunately, many doctors are too busy to read the journals of even their own specialty, and they keep current by reading or listening to the medical reporting

of such major outlets as the *New York Times*, *Chicago Tribune*, *Wall Street Journal*, CNN, and National Public Radio—media that have come to rely on the Center as a credible broker of news about behavior and health.

## Other Publications

Because many journalists lack the time to track and report comprehensively on complex biobehavioral and psychosocial issues, the HBNS also publishes a monthly report called *Facts of Life*, which summarizes a range of research relevant to a given health topic for use as background material for reporters and as copy that can be used whole or in part. Recent topics have included migraine headache, fibromyalgia, posttraumatic stress disorder, and obesity—all from the point of view of how behavior influences our health.

And through an electronic newsletter, the HBNS reaches thousands of members of the scientific community with news about funding opportunities, relevant government policy, and interdisciplinary research.

The Center for the Advancement of Health recognizes that while reporters need to know more about science, researchers also need to know more about reporters. As a result, the Center published in 2000 a popular pamphlet, *Communicating Health Behavior Science in the Media: Tips for Researchers*. It was a compilation of the best advice available from reporters themselves and communications professionals. In recent years, the Center has presented workshops for researchers to help them develop media outreach skills and strategic plans to get their research into the hands of the people who need it—the public.

## CENTERS FOR DISEASE CONTROL AND PREVENTION

The mission of the Centers for Disease Control and Prevention (CDC; 2003), the nation's leading agency for public health, is to make people safer and healthier. Headquartered in Atlanta with a workforce of over 8,500 employees across the country and throughout the world, CDC works to promote health and quality of life by preventing and controlling disease, injury, and disability. This work is accomplished through the many partnerships that CDC has developed with both public and private entities. By working with other health and community organizations, CDC carries out surveillance, monitoring public health standards, detecting and investigating health problems, conducting research to enhance prevention, developing and advocating sound public health policies, implementing prevention strategies, promoting healthful behavior, fostering safe and healthful environments, and providing leadership and training. Because disease permeates borders in an increasingly mobile world, CDC has a critical role in protecting the health of individuals through rapid investigation of disease outbreaks, whether they occur in the United States or in other countries. CDC also provides credible information to enhance health decisions, ensuring that the information is not only up-to-date but is accessible and meaningful to those it is meant to serve.

CDC is one of the major operating components of the U.S. Department of Health and Human Services. CDC's major organizational components respond individually in their areas of expertise and pool their resources and expertise on cross-cutting issues and specific health threats. The agency is comprised of these 12 organizational components:

*National Center on Birth Defects and Developmental Disabilities* (NCBDDD) provides national leadership for preventing birth defects and developmental disabilities and for improving the health and wellness of people with disabilities.

*National Center for Chronic Disease Prevention and Health Promotion* (NCCDPHP) prevents premature death and disability from chronic diseases and promotes healthy personal behaviors.

*National Center for Environmental Health* (NCEH) provides national leadership in preventing and controlling disease and death resulting from the interactions between people and their environment.

*National Center for Health Statistics* (NCHS) provides statistical information that will guide actions and policies to improve the health of the American people.

*National Center for HIV, STD, and TB Prevention* (NCHSTP) provides national leadership in preventing and controlling human immunodeficiency virus infection, sexually transmitted diseases, and tuberculosis.

*National Center for Infectious Diseases* (NCID) prevents illness, disability, and death caused by infectious diseases in the United States and around the world.

*National Center for Injury Prevention and Control* (NCIPC) prevents death and disability from nonoccupational injuries, including those that are unintentional and those that result from violence.

*National Immunization Program* (NIP) prevents disease, disability, and death from vaccine-preventable diseases in children and adults.

*National Institute for Occupational Safety and Health* (NIOSH) ensures safety and health for all people in the workplace through research and prevention.

*Epidemiology Program Office* (EPO) strengthens the public health system by coordinating public health surveillance; providing support in scientific communications, statistics, and epidemiology; and training in surveillance, epidemiology, and prevention effectiveness. EPO manages the Community Preventive Services Task Force work that produces the evidence-based best practices guides (The Community Guide, 2003).

*Public Health Practice Program Office* (PHPPO) strengthens community practice of public health by creating an effective workforce, building information networks, conducting practice research, and ensuring laboratory quality. Within PHPPO is an Office of Extramural Prevention Research that makes investigator-initiated grants on social and behavioral issues in health with a particular emphasis on participatory research approaches to link research and practice.

*Office of the Director* (CDC/OD) manages and directs the activities of the CDC; provides overall direction to, and coordination of, the scientific and medical programs of CDC; and provides leadership, coordination, and assessment of administrative management activities.

CDC performs many of the administrative functions for the Agency for Toxic Substances and Disease Registry (ATSDR), a sister agency of CDC, and one of eight federal public health agencies within the Department of Health and Human Services. The Director of CDC also serves as the administrator of ATSDR.

CDC recognizes the value of the behavioral and social sciences as part of its mission, and these disciplines play a vital role in the work of each center, institute, and office. In 1995, CDC established the Behavioral and Social Sciences Working Group (BSSWG) to raise awareness and to further the integration of behavioral and social science into research and prevention activities. With a membership of more than 300 individuals across CDC and the support of CDC's associate director for science, BSSWG has the following goals:

- To further the understanding and utilization of behavioral and social science at CDC and in public health
- To promote and ensure excellence in CDC's behavioral and social science research
- To facilitate communication, collaboration, and partnership among CDC behavioral and social scientists and other scientists and staff at CDC with an interest in behavioral and social science
- To facilitate CDC's recruitment and retention of behavioral and social scientists
- To further the professional development and advancement of behavioral and social scientists at CDC

The behavioral and social sciences encompass several disciplines, each with a variety of theoretical perspectives to explain events. Disciplines at CDC include sociology, psychology, anthropology, health education, economics, and psychiatry. Both qualitative and quantitative methods are used to understand behavioral and social processes that influence health and illness. Like all research at CDC, behavioral and social science research ranges from basic to applied. Applied research includes evaluation studies to examine the effectiveness of existing programs and the development, design, testing, and implementation of new interventions. Monitoring of key behavioral outcomes through surveillance systems is another common focus of applied research at CDC.

Two examples from the more than 300 research activities at CDC that involve the behavioral and social

sciences illustrate just a small portion of these activities. The first is the Behavioral Risk Factor Surveillance System (BRFSS), which operates out of the National Center for Chronic Disease Prevention and Health Promotion. The BRFSS, a state-based system of health surveys, was established in 1984 in 15 states. Using a standard core questionnaire and monthly telephone interviews, the BRFSS collects data on health risk behaviors, preventive health practices, and selected health conditions from a sample of adults in each participating state. Data are currently collected in all 50 states, the District of Columbia, and three U.S. territories. Key data include information on alcohol and tobacco use, diet, hypertension, injury control issues such as seat belt and bicycle helmet use, vaccination, health care coverage, and participation in cancer screening. Among several uses, the data are important for assessing trends, measuring progress in meeting health objectives, and evaluating programs and policies (BRFSS, 2003).

Another example is Project RESPECT, which was carried out by the NCHSTP. This project was designed to evaluate the efficacy of HIV prevention counseling in changing high-risk behaviors and preventing new sexually transmitted diseases (STDs). A randomized controlled trial was conducted at five inner-city clinics among heterosexual STD patients and included prevention interventions aimed at increasing risk awareness and condom use. Early analyses found that patients who received counseling interventions rather than brief STD messages had significantly higher condom use in the following 3 months and an approximately 30% reduction in new STDs in the following 6 months (Project RESPECT, 2003).

## CEREBROVASCULAR DISEASE: PSYCHOSOCIAL ASPECTS

---

Stroke is the third leading cause of death and the leading cause of adult disability, affecting an estimated 700,000 new persons a year in the United States. As a disease of sudden onset that damages the brain, stroke has the ability to rapidly and catastrophically throw all the psychosocial features of one's life into chaos and upheaval. To a greater extent than perhaps any other condition, stroke can have profound ill effects on cognition, personality, memory, social functioning, physical functioning, mental health, and work life. We briefly review the progress that has been made in understanding the role that psychosocial and behavioral factors play in the onset and course of stroke and stroke recovery. Attention is also paid to the impact of stroke on psychosocial functioning. Finally, intervention research, while somewhat limited compared to other conditions such as arthritis or heart disease, is briefly reviewed. The theme of this entry is that stroke is an ideal "strategic site" for the study of psychosocial factors and health, and that a greater understanding of the role of psychosocial factors will advance theory, research, and clinical practice in stroke.

### IMPACT OF PSYCHOSOCIAL FACTORS AND STROKE ONSET

In theory, psychosocial risk factors for stroke should be similar to those that have been demonstrated in coronary heart disease. Both conditions arise from vascular disease that can involve thrombosis, hemorrhage, coagulation disorders, and various disease processes that lead to ischemia. However, many of the psychosocial risk factors that have been found to be robust predictors of heart disease have not been clearly demonstrated in stroke. This constitutes something of a puzzle. An example is the work on stress. Factors such as work stress, stressful life events, and so forth have produced very mixed results. Some studies suggest an increased risk for those living stressful lives, but the evidence is generally weak. There is fairly consistent evidence that depression and depressive symptoms are associated with increased risk of stroke, especially for stroke mortality.

### Psychosocial Factors and Stroke Course

While the evidence in favor of an etiologic role for psychosocial factors and stroke is less than clear, a great deal of evidence suggests that a wide range of psychosocial and behavioral factors influence the recovery trajectories of stroke survivors. The main variables that have been studied include social support (especially emotional support), social network ties, and family function broadly defined. The bulk of this evidence suggests that social support from family and friends plays an important role in boosting functional recovery and social participation after stroke. Emotional support appears to be unconditionally positive, whereas instrumental support can be a double-edged sword. High levels of instrumental support are associated with worse outcome in some studies, due perhaps to failure to control adequately for health status or stroke severity, or because high instrumental support means that caregivers are overfunctioning in their role and that patients who are overly protected or understimulated have worse outcomes. Overprotection can also increase the risk of poststroke depression, perhaps by undermining the autonomy of the stroke survivor. The reasons for the strong association between social support and functional recovery are not entirely clear, but appear to be explained by a number of mechanisms, including greater treatment adherence, higher activity levels, better mood, and higher motivation for recovery. A related and strong finding is that the presence of a support network offers robust protection against nursing home placement after hospitalization for stroke.

### The Impact of Stroke and Psychosocial Functioning

Stroke has a significant emotional, social, and economic impact on survivors and their families. Affective and personality changes, aphasia, and cognitive impairments after stroke are the cause of much disruption in family relationships, resulting in heightened conflicts and loss of supportive ties. Family caregivers are at elevated risk for depression, caregiver burnout, social isolation, and increased physical symptoms. Social isolation, decreased participation in leisure activities, and sexual dysfunction appear to be common problems for both stroke survivors and family caregivers. On the other hand, a few studies report positive effects of stroke, in particular on family function and caregiver well-being.

### Psychosocial Interventions Poststroke

To date, at least seven randomized trials have been conducted testing various psychosocial intervention models designed to foster improved outcome after stroke. The results of these trials have, in large part, been disappointing. Two of these trials failed to change the trajectory of recovery, most likely because the interventions occurred too late (12+ months post-stroke). Two other trials were underpowered to detect differences in functional recovery due to small sample sizes. Several of the other larger trials focused on mobilizing formal community-based support services rather than on optimizing the naturally occurring social support found in the family. Given that these community-based programs have themselves not been shown to be effective in promoting more optimal stroke recovery, improved mobilization of these resources may not be an effective strategy. Finally, several of the studies involved relatively low-intensity interventions with fewer than five client contacts or interventions lasting a short time (fewer than 5 months).

### SUMMARY AND CONCLUSIONS

Stroke is a strategic site for the study of the effect of psychosocial and behavioral factors on disease onset and course. While stroke has been studied less extensively than cardiovascular disease, a strong case can be made that psychosocial factors play an important role, especially in stroke recovery. The strongest evidence suggests that an optimal mix of social support and strong social networks is an important component of rehabilitation. The efficacy of psychosocial intervention for stroke prevention or rehabilitation has not yet been demonstrated. More qualitative and quantitative research is needed on the factors that place persons at increased risk for stroke onset, predict poor recovery, or result in improved outcomes.

## CHILD ABUSE, CHILD NEGLECT, AND HEALTH

---

Both child abuse and child neglect are worldwide problems that impair the health and welfare of children and adolescents. Consequences often impede children's growth and development, and effects can be chronic, sometimes affecting individuals throughout their lifetime. The World Health Organization first recognized child abuse as a major public health problem in 1997, indicating that its elimination is a relatively recent but vital addition to their agenda of improving human health and well-being across the globe.

Perpetration of child abuse and neglect is thought to result from a complex combination of individual, family, community, and societal factors. At the individual level, some characteristics of caregivers who abuse or neglect children include mental health problems, including substance abuse, and a caregiver's own history of witnessing violence or being a victim of child abuse or neglect in the past. At the family level, violence between adult caregivers is a risk for child abuse and neglect. High levels of stress from financial or employment problems are other family risk factors. At the community level, cultural norms

about treatment and nurturing of children may affect the prevalence of child abuse and neglect. For example, widespread acceptance of high levels of community violence and/or use of severe physical punishment has been associated with higher prevalence of child abuse. However, social networks may protect children from abuse and neglect in that they help caregivers provide safer, healthier environments for children. At the societal level, countries engaging in wars or ongoing conflicts have rates of child abuse and neglect that escalate as the conflict grows and mass displacement occurs.

There is ongoing debate over how to define different types of child abuse and neglect in reliable, valid, and useful ways. Four general categories are currently recognized: (1) physical abuse, (2) sexual abuse, (3) neglect, and (4) emotional abuse. The most tragic consequence of child abuse and neglect is death of a child; in 1999, it was estimated that 1,100 children died from abuse and neglect in the United States, reflecting a rate of 1.62 children out of every 100,000 children in the population. This rate has remained stable since 1995.

### CHILD PHYSICAL ABUSE

Child physical abuse is most simply defined as an attack on a child that results in or is very likely to result in an injury. However, other definitions include physical assaults that may not result in physical injury. For example, caregivers may be charged with physical abuse if they use corporal punishment (such as spanking and hitting with objects) more frequently and severely than that allowed by cultural norms for punishment of children. Certain physical acts cause more serious injuries, depending on the age of the child; an infant hit on the head may sustain a serious injury such as a broken skull, while an older child hit with similar force might sustain a bruise. A relatively rare form of child physical abuse is Munchausen syndrome by proxy (also known as factitious disorder by proxy), in which a caretaker feigns illness in the child repeatedly in order to gain attention from medical staff, thereby assuming the “sick role” by proxy. The result is numerous unnecessary medical procedures performed on the child that can be harmful and in some cases fatal.

Although it has existed for centuries, the recognition of child physical abuse as a problem by the medical and public health communities began in 1962

with the publication of a landmark paper called *The Battered-Child Syndrome*. Armed with evidence from decades of studies on fractures and bruises among children, Kempe and his colleagues surveyed hospitals and district attorneys and measured the extent of the problem of injuries inflicted on children by their caretakers. The most recent government estimate of the rate of child physical abuse cases reported to authorities in the United States is 2.5 per 1,000 children.

### CHILD SEXUAL ABUSE

Obtaining consensus on a definition of child sexual abuse is such a challenge that a body of literature exists focusing on just its definition. For the purposes of this discussion, the following definition will be used from the U.S. Federal Government’s Child Abuse Prevention and Treatment Act (CAPTA) (42 U.S.C.A. 5106g):

- The employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct or simulation of such conduct for the purpose of producing a visual depiction of such conduct; or
- The rape, and in cases of caretaker or inter-familial relationships, statutory rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children.

Current recognition of child sexual abuse as a serious public health issue dates back to several prevalence studies among college and community samples in the late 1970s and early 1980s. Today there are hundreds of studies of its prevalence and consequences. Nationally representative prevalence estimates in the United States range from 0% to 16% among men and 3% to 27% among women as measured by surveys. In 1999, the rate of child sexual abuse cases that were substantiated by government agencies was 1.3 children per 1,000 children.

Repeatedly throughout the 20th century, awareness of the problem of child sexual abuse rose and then was suppressed by the negative reaction it elicited. The most notable example was Sigmund Freud’s 1896 “seduction theory,” which purported that child sexual abuse was the cause of many psychiatric problems among his patients. Under pressure from colleagues, he later recanted his theory and insisted that his

patients' accounts of childhood sexual assaults were fabricated and due to fantasy. Despite the proliferation of scientific findings about child sexual abuse in the 1970s, there was a formidable backlash in the newspapers, courts, and clinics in the 1980s, with critics arguing that child sexual abuse was being overreported and that the problem was overdramatized. Currently, the high prevalence of reported child sexual abuse by Catholic priests and the subsequent protection of these perpetrators by church officials is dominating the media, bringing renewed credibility to the problem as serious and hidden.

## NEGLECT

Childhood neglect may take many forms. At its most basic definition, neglect refers to deficiencies in caretaker responsibilities that result in physical and/or psychological harm to a child. Obligations of caregivers include meeting the basic needs of a child such as providing adequate food, shelter, and clothing, as well as the ability to attend school and receive developmentally appropriate supervision, necessary medical care, affection, and protection from harm. Abusing drugs and/or alcohol during pregnancy is sometimes considered prenatal neglect. Neglect is the source of the most child fatalities and has the highest incidence rate of substantiated cases out of the four categories of child abuse and neglect. In 1999, there were 6.5 cases of neglect substantiated by U.S. government agencies for every 1,000 children.

## EMOTIONAL ABUSE

Emotional abuse, also referred to as psychological maltreatment, is a relatively new area of study in the field of child abuse and neglect. Examples of emotionally abusive behaviors include verbal abuse, belittlement, symbolic acts that terrorize a child, lack of emotional availability by caregivers, and anything else that results in the impairment of a child's developing competence. Allowing a child to witness violence in the home is sometimes considered emotional abuse. Some suggest that emotional abuse takes five forms: rejecting, isolating, terrorizing, ignoring, and corrupting. To become a substantiated case, the emotional abuse must be sustained and repetitive. Substantiated cases of emotional abuse were reported to government agencies in 1999 at a rate of 0.9 per 1,000 children.

## CONSEQUENCES FOR MENTAL HEALTH AND BEHAVIOR PROBLEMS

Child abuse and neglect affect children in many deleterious ways. Numerous studies of maltreated children have found evidence of disrupted growth and development, with deficiencies in emotional, cognitive, and social development as well as in physical development and functioning.

Physical consequences associated with abuse range from minor bruises to burns, broken bones, brain damage, and at its most tragic end, death. Neglect can affect brain development, as well as cause general failure to thrive. Consequences of neglect may take the form of nonorganic failure to thrive in infancy, or as deprivational dwarfism as the children get older but remain small in stature because of the absence of proper nutrition.

There are myriad psychosocial and behavioral consequences as well. If a child is neglected in early stages of development, the lack of attachment between the child and his or her caregiver may affect the child's expectations of adult availability, trust, and social relationships throughout the life course. As children reach adolescence and adulthood, a history of maltreatment may lead to difficulties in school performance and low self-esteem. Participation in high-risk behaviors, including risky sexual behavior, abuse of alcohol and other drugs, and attempting and/or completing suicide, have also been linked to a history of child abuse. Abused and neglected children are at higher risk for arrests as juveniles as well as in adulthood, including arrests for violent crimes. Studies of incarcerated women have shown extraordinarily high rates of child abuse and neglect within prison populations.

Child abuse and neglect are also associated with numerous mental health problems. For example, in a nationally representative sample of the United States, child sexual abuse was associated with 14 subsequent mood, anxiety, and substance use disorders among women, and 5 among men. Conduct disorder, oppositional defiant disorder, depression, and generalized anxiety disorder are a few of the psychiatric problems associated with physical abuse among children and adolescents in a community-based probability sample. Emotional abuse may result in serious mental health problems as well, though its long-term consequences have yet to be studied.

If maltreatment is identified in a timely manner, there are efficacious treatment options that can prevent sequelae from affecting children across their

life span. However, many children never receive treatment. Still, some children and adults are resilient to the negative effects of child abuse and neglect. Protective factors such as strengths and supports both within a child and in a child's social environment may affect this resiliency. Gains have been made in development of efficacious treatment strategies of those who have suffered from child abuse and neglect. However, true primary prevention entails prevention of perpetration of the abusive and neglectful behaviors; research into efficacious primary prevention strategies is currently in infancy.

—Beth E. Molnar

for the individual and the least amount of disruption of daily life. Implicit in the concept of chronic disease is the idea that no cure for the given illness is available and the condition must be managed to reduce its impact on the patient, family, and society.

Management strategies comprise an individual's means to keep the disease and its effects under control (Clark, 1998; Karoly & Kanfer, 1982). These strategies may be effective or ineffective and may be consistent with clinicians' recommendations or not. Some people left to themselves will derive ways to achieve disease control that physicians or health educators would applaud (e.g., a susceptible asthma patient removing environmental precipitants to symptoms from the living quarters). Many do not (e.g., the person with asthma overusing bronchodilators in an effort to reduce symptoms). Effective disease control requires a strong partnership between patient, family, and clinician and adequate support from the health system and community to the individual who must manage the condition from day to day. Disease management is undertaken in full recognition that actions will not eliminate the disease but reduce its impact, for example, prolong life, enhance functioning, and in some instances reduce costs.

Similar themes run across definitions of chronic disease management by the patient (Creer, Levstek, & Reynolds, 1998; Karoly & Kanfer, 1982). First, 90% to 98% of day-to-day management is carried out by the patient. Second, recommended regimens involve a changing and complex set of behaviors and are not all-or-none phenomena (Glasgow & Eakin, 1998). Third, the context (setting and conditions) in which one manages influences the strategies utilized (Creer et al., 1998). Fourth, effective management by the patient requires a shift from well-established, habitual or automatic but ineffective responses to problems toward systematic long-term effective control. Long-term success entails attention to internal and external factors and use of cognitive processes to increase effectiveness (Karoly & Kanfer, 1982). Fifth, unless psychopathology or severe physical limitation is present, individuals can learn to improve their management of disease (Clark et al., 1986).

---

## CHRONIC DISEASE MANAGEMENT

---

Disease management means taking actions to ensure the best possible level of health and functioning

### DESCRIPTION

Until chronic diseases became the primary concern of developed countries, both professionals and patients, used to dealing with acute conditions,

**Figure 1** Concentric Circles of Influence

believed and behaved as if the manager of illness was the physician (or other relevant clinician) (Clark et al., 1995; Wagner, Austin, & Von Korff, 1996b). In recent years, however, it has become accepted that patients are the managers of their conditions. Of course, patients cannot do the job alone, as many aspects of disease control lie outside their ability or authority. Figure 1 illustrates the circles of influence on the individual trying to keep the effects of illness to a minimum (Clark et al., 1995).

The most influential is the family (Wasilewski et al., 1988), as members are in closest proximity to the patient and often, particularly in the case of a child, actually perform management tasks on behalf of the patient. Clinical expertise is also central to effective disease management (Clark et al., 2000). Most if not all chronic diseases require partnership between the physician and patient, with the clinician providing the best possible therapeutic regimen as well as the counseling and education that enables the patient to carry

through the clinical recommendations (Clark et al., 1995). The actions of the individual physician (or nurse or related clinical professional) are to a great extent influenced by the procedures of the organizations that provide and/or handle payments for clinical services. The availability, structure, policies, and resources of health provider organizations have a significant impact on how enabled or not a patient is in efforts to manage chronic disease. Other people in the social environment of the person with a chronic condition (work, school, and home) help or hinder effective management, as do individuals and organizations in the wider community. Communitywide policies and resources also have an effect.

The extent to which these circles of influence are mobilized in the direction of conducive and productive support of the person managing illness dictates the degree of disease control. Control is usually measured at an individual level (e.g., level of symptoms or side effects, day-to-day functioning, quality of life) and on a communitywide basis (e.g., rates of morbidity or mortality in a given population).

## RELEVANCE

Effective chronic disease management is of central importance in most countries of the world, even those where infectious disease continues to predominate. Leading causes of death around the world include heart disease, cancer, and stroke. Other diseases, although less likely to lead to early death, are costly in human and economic terms. Arthritis, diabetes, and asthma are good examples, as are Parkinson's disease and cystic fibrosis. HIV/AIDS, although an infectious disease that leads to premature death, is somewhat amenable to therapies that slow its progression and as such is also considered a chronic condition.

The human and economic costs of chronic disease are enormous. In the United States alone, heart disease kills 268 people per 100,000 population each year. Cancer causes the death of 203, and stroke another 61. Chronic obstructive pulmonary diseases kill 46 people per 100,000, diabetes 25, Alzheimer's 17, and kidney diseases 13 (National Center for Chronic Disease Prevention and Health Promotion, 2002). As noted, other diseases significantly debilitate individuals and families and cost billions of dollars annually in direct health service costs and additional billions indirectly because of (for example) missed work or school.

## DISTINGUISHING MANAGEMENT TASKS FROM SELF-REGULATION

Management skills and cognitive and behavioral processes that enable one to learn and use the skills are sometimes confused. To manage a disease, for example diabetes, certain tasks must be undertaken (e.g., determining glucose levels, using and adjusting medicines, engaging in regular exercise). However, the means by which an individual develops the management strategies designed to achieve these is self-regulation. Regardless of disease and the disease-specific tasks required of the individual to manage it, the same underlying cognitive and behavioral processes are likely at work. The person managing the condition must be observant of the factors influencing his or her management efforts, be able to exercise judgment (using some form of criteria) to choose between alternative actions, try out and realistically assess optional management strategies (i.e., determine if actions produce results), and have a sense of confidence in his or her ability to continue the action over time. Increasingly, research suggests that interventions that focus on these underlying cognitive and behavioral processes produce desired outcomes for people with chronic disease.

### Management Tasks of Stakeholders Associated With Disease Control

In considering the functions that comprise disease management, it is helpful to think about the stakeholder groups that take them: patient and family, health care professionals, health service organizations and systems, and communities or, writ large, societies.

*Patient and family tasks.* Central to the control of chronic conditions is the ability of individuals to learn and apply effective disease management strategies (Clark, Gong, & Kaciroti, 2001). Two categories of strategy are needed: those related to (1) prevention of episodes or flare-up of symptoms (e.g., changes in behavioral patterns, physical activity, smoking) and (2) management and reduction of symptoms when they occur.

Effective management by the patient and family evolves from the patient's observations, judgments, and reactions in light of the influence of internal and external factors, an important external factor being clinical recommendations. Implementation and

modification of therapies (medicine related, as well as nonpharmaceutical aspects of management such as diet or exercise patterns or levels of stress) best result from a combination of good medical advice and the patient working out how best to follow that advice on a day-to-day basis. Periodic interaction with the clinician and fine-tuning of the therapeutic recommendations are crucial.

As management of chronic disease by the patient almost always involves tasks using a prescribed medicine, the clinician needs to give the patient guidelines or an action plan to use to adjust medicines at home as needed. Some treatments (e.g., particular diabetes regimens) include complex tasks requiring continuous attention (Enzlin, Mathieu, & Demyttenaere, 2002). Others (e.g., some forms of heart disease) may require only one medicine a day.

When managing a chronic disease, the patient and family must learn enough about its natural history to observe, judge, and react appropriately to management challenges, that is, they must know the critical concepts relevant to disease control and learn the related management skills. The involvement of the family in day-to-day management is more frequently needed when the patient is a child. Even as a child, however, the patient must be allowed to play an active role in his or her disease management to evolve effective prevention and control strategies.

An extensive body of literature describes the role and significant influence of partners, parents, children, and siblings on the management efforts of a chronically ill person. And although families play an important role, most know from personal experience, as well as research, that family members can be a help or can deter disease management (Wasilewski et al., 1988). Disease control entails mobilizing families to be of the most positive help to patients.

*Tasks of health professionals.* Of crucial importance in disease management is the clinical community, particularly the physician primarily providing the patient's medical care. For over 50 years, a voluminous literature on patient-physician relationships has accumulated describing the interactions between the two (Roter et al., 1998). The kind of health care system (Wagner et al., 1996b), the role of the clinician, and the set of clinical skills needed to help enable patients to manage chronic disease (Clark et al., 1995) have been acknowledged as fundamental to a patient's success.

As noted, chronic disease management requires a partnership between the patient and clinician, and disease is unlikely to be controlled unless that partnership exists (Guidelines for the Diagnosis and Management of Asthma, 1997). Yet many in the clinical community need to learn how to assist their patients to manage better (Cabana et al., 2000). This is rarely a major focus of clinical training, even though an accepted and central role for most practitioners is encouraging and enabling effective disease management by their patients.

The goal for the health professional is to enable the patient to keep the condition under the best possible control to prevent deterioration and the negative effects of disease on the patient's physical and psychosocial functioning. When considering how clinicians interact with their chronically ill patients to achieve this end, we can categorize at least three types of clinical tasks. The first task is to tailor the most appropriate and effective therapeutic regimen for the individual. Here it is hoped that the clinician will be aware of and able to use therapies that are the standard of practice.

The second task is communication and counseling. In most chronic diseases, once the optimum medical regimen is determined, the clinician's role shifts from diagnostics and therapies to patient guidance and coaching. The success of the treatment plan (and an important measure of clinical performance) depends on how well the patient manages a disease on a day-to-day basis. Studies have shown that how clinicians interact with their patients influences health outcomes (Clark et al., 2000). Ten techniques clinicians can use have been shown to enhance communication with and generate positive results for patients. Clinicians can achieve results by (1) showing nonverbal attentiveness, (2) giving nonverbal encouragement, (3) giving verbal praise for things done well, (4) maintaining interactive conversation, (5) finding out underlying worries/concerns, (6) giving specific reassuring information, (7) tailoring the medication schedule to the family's routine, (8) reaching agreement on a short-term goal, (9) reviewing the long-term therapeutic plan, and (10) helping the patient to use criteria for making decisions about disease management (Clark et al., 1995).

A third task for the clinician is to provide specific messages that make clear the critical concepts and basic factual information required for patients to understand and follow the therapeutic recommendations.

The problem of providing information that is irrelevant to a patient's personal concerns or information of a type that does not affect behavior has been discussed in the literature (Caplin & Creer, 2001; Creer et al., 1998; Heisler, Bouknight, Hayward, Smith, & Kerr, 2002). In most if not all of the major chronic diseases, there is a core of salient concepts linked to changes in patient behavior that comprise the foundation for management (Heisler et al., 2002; Lorig, Mazonson, & Holman, 1993). These must be provided to the patient.

*Tasks of health care organizations and systems.* There is little doubt that the setting providing patient care and the means by which care is paid for affect the health and functioning of the person with chronic disease. Means by which clinical procedures, supportive services, and other resources are directed to diagnosis and treatment are often referred to as disease management by the health care system.

Deficiencies in the delivery of routine care for patients with chronic illness have been identified as contributing to suboptimal outcomes (Wagner et al., 1996b). These include irregular or incomplete assessment or inadequate follow-up of patients, inadequate or inconsistent patient education and feedback, omission of effective interventions or use of ineffective ones, and failing to detect or inadequately managing a patient's psychosocial distress.

Although few studies have focused on the chronic disease management tasks associated with health care systems, five organizational elements (Wagner, Austin, & Von Korff, 1996a) have been posited as maximally responsive to the needs of the chronically ill. The first element is using evidence-based protocols for managing patients. This element requires a shift in clinical practice away from habit or use of favored but unsubstantiated therapies toward interventions that have been subjected to clinical trials and proven effective. The second is reorganization of practice systems and provider roles. This element requires reconsideration by the health care organization of how to effectively deliver primary care, make appointments, allot clinical time, delegate tasks, manage data, and so on. These planned improvements have been referred to as "practice redesign" (Wagner et al., 1996b). The third is ensuring timely availability of relevant expertise, a factor that is partly dependent on the resources available from insurers for reimbursing the cost of expertise. The fourth element is more

organized and readily available clinical information. This element ranges from making up-to-date data available on individual patients to innovations in telemedicine. The final element is building into the organization improved patient education. Improved patient education includes (a) implementing proven patient education programs, and (b) ensuring that individual education and counseling is provided to patients by clinicians.

A problem in assessing the role and success of clinicians of all types in fostering effective disease management in their patients is that research has not separated the effects of clinical behavior from the organizational features of the practice environment. While both are necessarily entwined, determining the relative contribution of each to important patient outcomes could enhance the design and delivery of interventions.

*Community (society, state, etc.) programs and policies.* As the circles of influence reach beyond families and clinicians to those in the day-to-day environment of the patient, people in the workplace or school need to understand what to do to support individuals with chronic disease. They must act to help in an emergency. They also need to recognize when their coworker or classmate needs some instrumental assistance or just some moral support and encouragement (Israel, Guile, Baker, & Silverman, 1994).

Community awareness and action are also important. Environmental measures are sometimes needed, for example, measures to reduce air pollution and other factors that exacerbate cardiovascular and lung disease. Conducive policy and regulation is needed, for example, enabling people to have access to medical care and to safe and effective pharmaceutical products. The important points here are that individual patients cannot control the range of influential factors on their own, and control of chronic disease goes beyond individual and clinical approaches.

Positive outcomes can result from actions of others in the community with a stake in disease control in support of those managing a chronic condition. For example, effective disease management by school children involves not only children with the illness but also school staff and classmates. Disease management education for children at school and education of their peers without a chronic condition has been shown to positively affect outcomes by creating more conducive social and physical environments (Clark,

2002; Shah et al., 2001). Other community venues work as the sites for enhancing disease management. Norris et al. (2002) reviewed educational interventions and concluded that there was sufficient evidence that these programs improved glucose monitoring by adults with Type 2 diabetes when offered in community gathering places (churches, community organizations, etc.).

Effective policy can greatly assist those with chronic disease. In some parts of the United States, for example, policymakers have changed school practices to allow children with asthma to use their medications at school. A child may be a very fine manager, but school regulations may prevent him or her from managing at the optimum level.

Financial policies can also enable or deter good management. For example, some insurance plans have recognized that related equipment must be available to patients managing disease to ensure a good outcome. In some policies, spacer devices are covered to enable young children with asthma to receive adequate doses of medicine, or essential equipment is made available to diabetics. However, these examples are too often exceptions. In few areas of the country are communitywide support systems and policies, access to high-quality preventive care, and adequate financial arrangements universally congenial to people with chronic disease.

## IMPROVING CHRONIC DISEASE MANAGEMENT

Although some good research has illustrated that individuals with chronic disease can improve how they manage a condition and other stakeholders can learn to be supportive, understanding the potential impact of interventions is limited by insufficient study. For example, a recent review (Barlow, Wright, Sheasby, Turner, & Hainsworth, 2002) examined 145 evaluations of programs to enhance management of 30 different chronic conditions. Approximately half of the studies were randomized controlled trials with very small sample sizes (e.g., 20-30 patients) and with short follow-up periods (typically 4-6 months). Such time frames are clearly inadequate, given the duration of most chronic conditions.

Nonetheless, consideration of the potential impact of interventions is aided by the growing interest in the past decade in evidence-based medicine. Much closer attention is paid these days to the actual health

outcome associated with various therapies and interventions thought to benefit patients. An outgrowth of this interest is the Cochrane Collaboration, an initiative in the United Kingdom supported by the National Health Service. The Cochrane Collaboration, by mobilizing researchers from around the world, has developed rigorous methods for searching databases (in all languages), selecting studies using strict criteria for inclusion (essentially well-conducted, randomized controlled trials and controlled clinical trials with adequate sample sizes), analyzing data in a standardized form of meta-analysis, conducting peer review, and making results available not only in peer-reviewed journals but also on the Internet, where periodic updates are provided.

Of late, Cochrane reviewers have turned their attention to disease management by patients, specifically asthma and arthritis. In both instances, interventions reviewed were associated with positive outcomes, for example, reduced hospitalizations, ER visits and unscheduled office visits, fewer absences from work or school, and decreases in symptoms. In short, over the past 20 years, evaluations of interventions to assist patients with the range of major chronic conditions have produced data to suggest that patients, families, and clinicians can be taught to manage disease more effectively. However, study of effective means to help patients is needed especially regarding the organization and financing of clinical health care.

## CHRONIC FATIGUE SYNDROME: PSYCHOSOCIAL ASPECTS

---

Fatigue is considered a nonspecific symptom because it can be indicative of several causes or conditions. It occurs in many physical and psychiatric

illnesses, as well as in response to medication or medical treatment or to temporary physical conditions or lifestyle. Chronic fatigue syndrome (CFS) has recently emerged as an illness whose primary symptom is chronic fatigue, but it is also accompanied by the various combinations of other symptoms, including sore throats, muscle pains, and unrefreshing sleep. CFS has its origins in the 19th century, with the condition known as neurasthenia. By the late 1800s, neurasthenia was one of the most frequently diagnosed illnesses; however, by World War I, the diagnosis of neurasthenia almost disappeared. By the beginning of this century, medical skepticism concerning this illness increased and neurasthenia began to be viewed as a psychiatric disorder rather than a neurological illness. In addition, neurasthenia patients were increasingly held in low esteem by medical personnel. The debate that occurred about 100 years ago, concerning whether neurasthenia was a disease of the body or mind, has reappeared with CFS.

## CASE DEFINITIONS

The original case definition of CFS, published in Holmes et al. (1988), defined CFS as the “new onset of persistent or relapsing, debilitating fatigue” that was “severe enough to reduce or impair average daily activity below 50% of the patient’s premorbid activity level for a period of at least six months.” In addition, a person had to have 8 or more of the 11 minor symptoms (e.g., sore throat, painful lymph nodes, unexplained generalized muscle weakness). However, use of the original case definition of CFS appears to have produced erroneous estimates of the extent of CFS comorbidity with psychiatric disorders.

In the United States, there was considerable dissatisfaction with the original Holmes et al. (1988) case definition because it was being inconsistently applied by researchers. In 1994, a new CFS definition was published (Fukuda et al., 1994). In this new case definition, a person needed to experience chronic fatigue that had a new or definite onset, that was not substantially alleviated by rest, that was not the result of ongoing exertion, and that resulted in substantial reductions in occupational, social, and personal activities. In addition, there needed to be the concurrent occurrence of four or more minor symptoms (sore throat, muscle pain, etc.). This new case definition required only four minor symptoms, whereas the previous definition required eight. The new definition of

CFS did not exclude people who have purely psychosocial, stress, or many psychiatric reasons for their fatigue. By broadening the CFS definition, it is important to ensure that those patients with solely a psychiatric disorder are not erroneously included within the CFS rubric, as including these types of patients in the current CFS case definition could seriously complicate the interpretation of studies.

## PSYCHIATRIC INSTRUMENTS

The Diagnostic Interview Schedule (DIS), a structured psychiatric instrument designed for use in community surveys, has frequently been used to assess psychiatric comorbidity in CFS samples. Unfortunately, this instrument was not designed for use with medically ill populations. As an example, if several physicians diagnosed a patient as having a medical disorder, but only one attributed the symptom to a psychiatric disorder, the item would be scored to count toward a psychiatric diagnosis. Many physicians still do not accept CFS as a legitimate medical disorder, so it is possible that many patients would have had at least one physician who diagnosed their medical complaints as being a psychiatric disorder, thus increasing the likelihood that people with CFS would receive a psychiatric disorder assessment.

In contrast to the rigid interview structure of the DIS, the Structured Clinical Interview for the *DSM-IV* (SCID) uses open-ended questions and all potential sources of information to encourage a thorough description of the problems by the interviewee. Use of the SCID is also limited to highly trained clinicians. A study by Taylor and Jason (1998) administered the DIS and the SCID to a CFS sample. Of individuals diagnosed with CFS, 50% received a current Axis I psychiatric diagnosis when using the DIS; however, only 22% received a current diagnosis when using the SCID. These findings suggest that high or low psychiatric rates in CFS samples may be a function of whether symptoms are attributed to psychiatric or nonpsychiatric causation.

## Etiology

Rather than conceptualizing CFS solely as a disease of the body or the mind, a biopsychosocial perspective provides a transactional model, one that suggests that complex interactions between multiple biological and psychological factors influence the onset of CFS and pathways to further illness or recovery.

The biopsychosocial model contends that there might be multiple pathways leading to the cause and maintenance of the neurobiologic dysregulations and other symptoms experienced by individuals with CFS. Depending upon the individual, these may include unique biological, genetic, neurological, psychological, and socioenvironmental contributions.

Clauw and Chrousos (1997) suggest that individuals who develop CFS might be genetically predisposed to develop this condition. It has been found, for example, that patients with CFS have parents with increased prevalence of cancer and autoimmune disorders when compared to control patients' families. It was also found that persons with CFS were significantly more likely to report a family history of autoimmune disorders when compared to a control group. Clauw and Chrousos further posit that susceptible individuals might evidence a number of organ-specific illnesses before finally progressing to develop CFS. Supportive data is also available for this thesis, as prior to developing CFS, patients have significantly more upper respiratory tract infections, lethargy, and vertigo than controls. Clauw and Chrousos also suggest that once the individual develops CFS, which can occur abruptly or slowly through viral infections or emotional stressors, there is a blunting of the hypothalamic-pituitary axis and instability of the autonomic nervous system. In patients with CFS, the biological stress response is blunted, and if exercise leads to a further drop in cortisol levels, this postexercise adrenal insufficiency could be responsible for the severe postexertional fatigue that patients frequently experience.

## Epidemiology

The first, and widely publicized, study of CFS epidemiology, from which the estimates above were derived, was initiated in the late 1980s by the CDC. Investigators requested physicians in four cities to identify their patients who had a group of specified fatigue-related symptoms. The minimal prevalence rates of CFS ranged from 2.0 to 7.3 individuals per 100,000 cases. This study was typical of the first generation of CFS epidemiological studies, which were based on physician referrals from hospital and community-based clinics. However, medical sociological studies have indicated that many low-income individuals do not have access to the health care system; therefore, it is inappropriate to estimate prevalence estimates solely from treatment facilities.

A second generation of epidemiological studies have used more community-based samples. As an example, Jason and colleagues (1999) attempted to contact a stratified sample of 28,673 households in Chicago by telephone. Of that sample, 18,675 individuals were screened for CFS symptomatology. The sample was stratified to ensure a representative sample of the diverse ethnic and socioeconomic groups comprising the Chicago general population. Based on the initial screening, participants with significant fatigue and CFS symptoms were selected to receive a psychological evaluation and medical examination. Approximately 0.4% of the sample was determined to have CFS, and rates of CFS were higher among Latino and African American respondents when compared to White respondents. These data suggested that there might be as many as 800,000 adults in the United States with this syndrome, suggesting that it is one of the more common chronic health conditions.

## Nonpharmacological Interventions

Cognitive-behavioral therapy with graded exercise constitutes a form of treatment for CFS, and this nonpharmacological intervention has been suggested as one of the more promising treatment approaches. Cognitive behavioral interventions deal with cognitive restructuring, coping skills, provision of psychological support, and illness education. It is still unclear whether these types of interventions influence the immune system. Miller and Cohen (2001) have proposed that patients might evaluate stressful experience as a significant threat and exceeding coping resources, and this might elicit negative emotional responses. These negative emotional responses cause distressed patients to engage in behaviors (e.g., decreasing physical activity, altering sleep patterns), which conceivably modify immune responses. In addition, negative emotional states might also activate the sympathetic division, whose fibers descend from the brain to lymphoid tissues (bone marrow, thymus, spleen, etc), and these fibers could release substances that influence immune responses. Distress also can activate the HPA axis, and hormonal products from these systems can dysregulate the immune system. Psychological interventions might modify the way stressful circumstances are appraised, and diminish the way negative emotional responses influence immune dysregulation. Relaxation, emotional-regulation training, and learning more adaptive coping responses might also decrease negative emotions.

## CONCLUSION

When a new disease syndrome emerges, such as CFS, studies on diagnostic criteria, epidemiology, and treatment approaches can help shape public policy decisions. Beliefs about the medical legitimacy of the illness may influence federal and state resources allocated for research, prevention, and intervention. Scientists have key roles to play in investigating issues of attribution as they relate to new disease syndromes such as CFS. If inappropriate use of the case definition leads to the inclusion of individuals who have a purely psychiatric condition, this heterogeneity of patients with CFS and psychiatric conditions will present difficulties in interpreting the results of epidemiological and treatment studies. A broad or narrow definition will have important influences on both CFS epidemiological and treatment studies.

## CHRONIC ILLNESS: PSYCHOLOGICAL ASPECTS

We place the bottom line at the top of this entry: Heterogeneity in adjustment to chronic illness is the rule rather than the exception. That is, adjustment is shaped by many intrapersonal and interpersonal processes and occurs across many life domains. Adjustment to chronic illness represents a process that unfolds over time, a process that cannot be described adequately without understanding the individual's life context. Identifying the psychological processes that affect adjustment outcomes is important for the design of clinical interventions aimed at reducing distress and life disruption.

## DEFINITIONS AND IMPACT OF CHRONIC DISEASE

The National Center for Chronic Disease Prevention and Health Promotion defines chronic disease as "illnesses that are prolonged, do not resolve spontaneously, and are rarely cured completely." According to this broad definition, more than 90 million Americans live with chronic diseases. This number is expected to increase as life expectancy increases and many diseases that were formerly considered as acute, including AIDS, are redefined as chronic. Chronic diseases shorten survival, are the leading cause of disability, and lead to economic, social, and psychological declines. Women, racial minority

populations, and people living in poverty are affected by chronic illness to a disproportionately greater degree.

From a psychological perspective, the definition of chronic illness is complex: When does one stop being a cancer patient? When treatment is completed? When there is no detectable cancer? When symptoms subside? Most medical researchers concur that the disease process must persist over at least several months to constitute *chronic* disease, but there is great variation in the rapidity of onset, degree of life threat, and extent of daily life disruption from symptoms and treatment. Although some of the consequences of chronic disease are sudden and obvious, such as the surgical excision of a body part, others are gradual and insidious, such as losing muscle strength, changes in family relationships, and a changed self-concept.

#### WHAT DOES IT MEAN TO ADJUST TO CHRONIC ILLNESS?

##### **Adjustment Involves Multiple Adaptive Tasks**

Despite the fact that there is wide variation in chronic illnesses, there are several central, common adaptive tasks of illness: keeping distress within manageable limits, maintaining a sense of personal worth, restoring relations with significant other people, enhancing prospects for recovery of bodily functions, managing pain and symptoms, negotiating the medical treatment environment, maintaining adequate relationships with health care professionals, and increasing the likelihood of attaining a personally valued and socially acceptable situation once maximum physical recovery has been accomplished. Shelley Taylor's theory of cognitive adaptation to threatening events emphasizes self-esteem enhancement and preservation of a sense of mastery over one's life, and adds resolution of a search for meaning ("Why me?") as a central adaptive task. Other tasks or goals involve resumption of paid employment or routine activities, mobility, and adherence to a treatment regimen.

##### **Adjustment Is More Than the Absence of Psychopathology**

The most often used markers of adjustment include the presence or absence of diagnosed psychological disorder, psychological symptoms, negative mood, and satisfaction in various life domains (marriage, work). Researchers examine health-related quality of

life in physical, functional, social, sexual, and emotional domains. The negative consequences of chronic illness have been emphasized, because identifying the psychological processes that adversely affect disease outcomes and psychological adjustment is important for designing psychological interventions.

The relative lack of attention to more positive outcomes has persisted until recent years, despite early observations that "many patients are remarkably resourceful even in the face of a catastrophic situation" (Hamburg & Adams, 1967, p. 278). Indeed, positive adjustment may more accurately represent the experience of most individuals with chronic illness than does psychopathology. Studies of long-term cancer survivors suggest that the greatest degree of distress and life disruption occurs within the first year after diagnosis (during initial treatment), with global adjustment indicators resuming pre-illness levels after that.

Researchers who study posttraumatic growth and resilience challenge the assumption that good adjustment is defined by a return to pre-illness levels of mental health or physical functioning. Instead, individuals can experience growth in self-awareness, interpersonal relationships, and enjoyment of life, or even make quantum life changes. Echoing many other personal accounts, three-time Tour de France winning cyclist Lance Armstrong said that cancer was the best thing that ever happened to him, as it made him take his sport more seriously. Through efforts to find meaning in their illness, many people with chronic illness are able to thrive and not simply survive.

##### **Adjustment Is a Dynamic Process**

As treatment demands, disability, and prognosis change over time, so do the adaptive tasks of illness. There is little evidence that adaptation follows a linear path. Medical advances (e.g., the development of anti-retroviral therapies for AIDS), unexpected changes in disease progression (e.g., a cancer recurrence or an arthritis flare), and shifts in the individual's life context (e.g., taking on new family or work roles) create more circuitous pathways to adaptation. Interpersonal interactions with friends and family also change over time, and can alternate between periods of relative independence and dependence. Thus, adjustment to chronic illness changes over time because of changes in one's medical situation, personal relationships, and life circumstances.

### Adjustment Must Be Embedded in the Life Context

Adjustment to chronic illness can be understood only in conjunction with the life context in which illness occurs. Demographic characteristics such as gender, age, and social class provide us with culturally acceptable modes of coping as well as constraints on one's coping repertoire. For example, processing and expressing emotions is more adaptive for women in particular contexts in part because it is seen as more socially appropriate. The onset of an illness that is "off-time" in the normative adult life cycle (e.g., being diagnosed with Parkinson's disease in your 30s) is likely to be more stressful than when the illness occurs "on-time." People are not prepared for the sudden life or bodily changes that illness brings, and relatively few age peers are experiencing the same life situation, so there are fewer individuals with whom to share concerns.

### Heterogeneity in Adjustment as the Rule

Research reveals substantial diversity in individuals' adjustment to chronic illness, with most reporting generally positive adjustment and the minority evidencing significant distress or life disruption. Few people with chronic disease manifest clinical levels of psychological dysfunction, although rates vary widely across studies. Chronic disease is likely to carry a more circumscribed impact for most people. Barbara Andersen has observed that cancer is more likely to produce "islands" of life disruption in particular life realms and at specific times than it is to result in global and persistent maladjustment.

## DETERMINANTS OF ADJUSTMENT TO CHRONIC ILLNESS

### Cognitive Appraisals

How individuals view their illness is a central determinant of subsequent actions, emotions, and adjustment. Cognitive appraisals include the degree of threat and potential for harm that the illness presents, how changeable or controllable the illness is, and a self-evaluation of one's coping resources. A man who believes that his diagnosis of prostate cancer is a death sentence is likely to make very different decisions regarding treatment than one who sees his cancer as curable, and the two men are likely to manifest distinct adjustment trajectories.

Perceiving a sense of control or mastery over one's life in general is associated with better adjustment outcomes unless the illness is medically uncontrollable, when relinquishing control is advantageous. Sense of control has predicted less angina in patients following coronary artery bypass grafts and better functional status following osteoarthritis surgery. Control appraisals also influence the choice of coping strategies; higher perceived control is associated with the use of more approach-oriented coping strategies. However, choosing a controllable target makes a difference: Cancer and arthritis patients' belief that they could control daily emotional and physical symptoms was a stronger predictor of adjustment than was perceived control over long-term disease progression.

### Coping Processes

How one copes with the illness makes a difference. Coping efforts may be focused on solving or minimizing concrete problems or directed toward managing the emotional distress created by those problems. Approach-oriented or active coping processes include information seeking, problem solving, seeking social support, actively attempting to identify benefits in one's experience, and creating outlets for emotional expression. Avoidance-oriented coping processes involve both cognitive (e.g., denial, distraction, suppression) and behavioral strategies (e.g., behavioral disengagement). Other processes, such as spiritual coping, potentially can serve either approach-oriented or avoidance goals.

The use and effectiveness of particular coping strategies are likely to vary over time and across specific adaptive tasks. Although avoidant coping may be useful at specific, acute points of crisis, it typically is associated with poorer adjustment over time. Coping through avoidance may involve harmful behaviors (e.g., alcohol use) that may impede other more effective coping attempts. Approach-oriented coping strategies often result in more positive adjustment outcomes, perhaps because they afford a sense of control.

### Personality

Personality or person-centered variables affect adjustment directly and through their influence on appraisal and coping processes. *Dispositional optimism*, or generalized expectancies for positive outcomes in life, has been related to both greater use of

problem-focused coping strategies and fewer symptoms of depression among ischemic heart disease patients, coronary artery bypass graft patients, early-stage breast cancer patients, and HIV-positive men. *Self-efficacy* (best exemplified by the motto of the Little Engine Who Could: "I think I can, I think I can") is also advantageous, predicting better management of symptoms, less pain, greater adherence to prescribed treatment, and more positive mood.

*Neuroticism* involves chronic negative affect (including anxiety, tension, sadness, frustration, and irritability) coupled with low self-esteem and high self-consciousness. Individuals high on this trait tend to complain of more symptoms, and it has been linked to increases in blood pressure, the development of coronary heart disease, premature mortality, length of survival, and, among HIV patients, more rapid deterioration of the immune system.

### Social Support

Most of the adaptive tasks of chronic illness require help or feedback from others. Thus, patients need an available and satisfying network of interpersonal relations on which they can count for both emotional sustenance and more practical help during periods of pain, disability, and uncertainty.

*Social support* refers to the processes by which interpersonal relationships promote psychological well-being and protect people from health declines, particularly when they are facing stressful life circumstances. Supportive behaviors can involve demonstrations that one is loved, valued, and cared for, and the provision of helpful information or tangible assistance. Although social support should not be dependent on network size, the networks and social activities of ill or disabled individuals are often restricted.

A wealth of research over the past two decades has demonstrated that interpersonal relationships are a strong predictor of adjustment to chronic illness. Patients receiving more support from friends and family exhibit greater self-esteem and life satisfaction, cope more effectively, and exhibit fewer depressive symptoms. This is robust across populations with different illnesses and of different durations. Social support operates through a number of physiological and cognitive pathways. Social support enables recipients to use more effective coping strategies: It helps patients come to a better understanding of the meaning of their illness, it increases motivation to take

instrumental actions, and it reduces the tension and emotional stress that may impede other (more effective) coping efforts.

Social support is most beneficial when it matches the characteristics of the stressor faced. For example, a recently diagnosed patient may desire concrete information to make a medical decision; a more disabled patient may prefer help with activities of daily living combined with companionship. *Who* is providing support also is important: Chronically ill people prefer to receive emotional support from family and informational support from medical personnel.

Most research has focused on the benefits of social support. But receiving, using, or requesting support has its costs. Patients experiencing pain and disability are very vulnerable to the effects of critical comments. The perception of network members as unreceptive to efforts to discuss stressful or traumatic events has been referred to as *social constraints*. Discussing stressful circumstances in a supportive, uncritical social environment allows people to process their emotions, maintain or reestablish a positive self-concept, and find meaning in the illness. Persons with breast, colon, and prostate cancer and persons with rheumatoid arthritis who perceive that others are unreceptive to hearing about their experiences have poorer psychological adjustment.

### Macrolevel Contextual Factors

Previously, we suggested that adjustment to illness must be understood in conjunction with the life context in which illness occurs. Several macrolevel factors have been shown to affect adjustment, including socioeconomic status (SES), culture, ethnicity, and gender. SES and race most likely affect adjustment indirectly through their influence on key environments, including the physical environment in which one lives and works and the social environment of interpersonal relationships. Studies of chronic illnesses such as cancer, heart disease, and arthritis have found that women are more strongly affected by the illness, even more so when they are in the caregiver role. But because many diseases vary in their prevalence among men and women, most studies sample respondents of only one sex, so we can't easily untangle gender effects.

Cultural worldviews supply blueprints for adaptation to illness—how meaning is given to events and which behaviors are appropriate in which situations. Culture determines whether one should follow the

advice of traditional medical providers or turn to culturally sanctioned healers (e.g., *curanderas*, *yerberos*). Cultural blueprints also shape cognitive appraisals of illness, guide treatment decisions, and determine how illness is expressed. For example, in Latina cultures, the condition of *nervios* blurs the distinction between physical and mental illness, and in some societies with high poverty rates or totalitarian governments, the expression of illness is a behavioral manifestation of powerlessness, particularly among women. Culture also may define the acceptability of particular coping responses, such as emotional expression or anger, and thus limit their value as adaptive mechanisms.

## SUMMARY

Chronic illness affects psychological and social functioning, but psychological and social variables also shape an individual's adjustment to the illness. Adjustment involves coping with multiple tasks of illness that involve coping with a changed self, changes in interpersonal relationships and future uncertainty. It is best conceptualized as a dynamic process that involves the interplay between persons and their environments. There is a good deal of heterogeneity in adjustment patterns, with most reporting generally positive adjustment and the minority evidencing significant distress or life disruption. Above all, there is not one way to successfully adjust to chronic illness; evaluation of adjustment must take the individual's life context into account.

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE: PSYCHOSOCIAL ASPECTS AND BEHAVIORAL TREATMENTS

---

Chronic obstructive pulmonary disease (COPD) is the fourth leading cause of death in the United States,

with annual health care costs of approximately \$27 billion. Patients with COPD frequently have concomitant symptoms of psychological distress, especially depression and anxiety, and may exhibit deficits in cognitive functioning, as demonstrated on standard neuropsychological tests. In addition, patients with COPD often experience reduced quality of life, reflected by impaired social relationships, diminished work performance, and reduced capacity for performing activities of daily living (ADL). Psychosocial aspects of COPD also may include smoking cessation, maintenance of nutritional balance, and medication compliance.

Medical treatment of COPD includes medications, surgery, and physical exercise. Patients with COPD are routinely treated with multiple medications, such as bronchodilators, inhaled steroids, oral steroids, and oxygen. Surgical treatments, including lung volume reduction surgery and lung transplant surgery, are also options for selected patients. However, the standard of care for patients with COPD now includes exercise rehabilitation; studies have documented multiple positive outcomes of exercise among patients with COPD. Rehabilitation programs often incorporate individual and group treatment sessions designed to address specifically the behavioral and psychological aspects of coping with COPD. This entry elaborates on the psychosocial components of COPD and the strategies for treating psychosocial problems among patients with COPD.

## WHAT IS COPD?

The COPD diagnosis may encompass any of three diseases—chronic bronchitis, emphysema, and asthma—all of which are characterized by expiratory airflow obstruction. Although these three diseases differ somewhat with regard to etiology and degree of related disability, the clinical symptoms frequently overlap, and often COPD patients are diagnosed with more than one of the three diseases. Asthma alone, however, would not be categorized as COPD because patients with COPD, unlike asthmatics, do not revert back to normal pulmonary functioning between episodes of breathing difficulty and they tend to be refractory to the drugs that relieve bronchospasm in most asthmatic patients.

Although many of the changes in lung function of patients with COPD (e.g., decreased lung capacity) resemble those of normal aging, the changes occur at

an accelerated rate for COPD patients. In addition, changes such as airway obstruction and pulmonary blood flow irregularities are markers of lung pathology that do not occur with normal aging. These latter changes eventually lead to decreased oxygen uptake in the bloodstream and, ultimately, a state of chronic hypoxia. The chronic hypoxia of COPD patients has been associated with physical limitations such as fatigue and deconditioning. Most patients with COPD become severely deconditioned and lose muscle mass due to reduced activity level.

## DEMOGRAPHIC/SYMPTOM

### PROFILE OF THE PATIENT WITH COPD

The typical patient with COPD is over age 60, with shortness of breath (dyspnea) during physical activity and chronic coughing. The primary risk factor for COPD is cigarette smoking, and most patients with COPD have an extensive history of smoking. However, COPD also may be diagnosed in nonsmokers due to a genetically inherited form of the disease (alpha-1 antitrypsin deficiency). Other risk factors for COPD include age and exposure to environmental contaminants (e.g., air pollution, workplace exposures). Although COPD has affected predominantly men in the past, the incidence among women has increased significantly in recent years, largely because the cigarette-smoking habits of women have become more similar to those of men.

Early in the course of COPD, dyspnea occurs only with physical activity, but as the disease progresses, dyspnea may be exacerbated by changes in weather, respiratory infections, and the exertion required for relatively mild ADLs such as dressing and showering. Dyspnea also may occur at times of emotional distress, such as when the patient is feeling anxious or extremely angry. Coughing may contribute to difficulty in breathing, and excessive coughing in public may be associated with social embarrassment. Because the onset and early progression of COPD is insidious, with symptoms usually worsening only gradually, patients may ignore symptoms until the disease becomes unmanageable or requires hospitalization.

## Psychosocial Functioning

Psychological distress associated with pulmonary disease may influence functional status and physical well-being, independent of disease severity. Recent

studies have documented that psychological factors are more strongly associated with mortality than medical factors such as disease severity and blood oxygenation levels. Thus, assessment and treatment of psychological factors are critical for effective treatment of the patient with pulmonary disease. Common psychological reactions among patients with pulmonary disease include anger, frustration, guilt, dependency, and embarrassment. However, depression and anxiety are the most frequently observed psychological reactions among patients with COPD.

### *Depression*

Depression in patients with COPD typically is characterized by hopelessness, a pessimistic outlook, reduced sleep, decreased appetite, increased lethargy, concentration difficulty, and increased social withdrawal. Depression in COPD patients may significantly limit daily functioning. Studies consistently report that depressed mood predicts behavioral, social, and mental functioning, and greater depressive symptoms have been associated with higher levels of impairment in ADLs. Although the correlation between depressed mood and disease severity is modest, depression may have an influence on daily functioning that is independent of pulmonary functioning and disease severity.

### *Anxiety*

Symptoms of anxiety are manifested in various ways, including accelerated speech, exaggerated body movements, and physiological signs of arousal such as tachycardia, sweating, and dyspnea. Most patients with COPD report symptoms of anxiety, and up to 37% of patients may experience one or more panic attacks. Dyspnea itself, in conjunction with a fear of suffocation and death, is a source of significant anxiety in this population. The emotional arousal of anxiety increases ventilatory demands on the body that may lead to hypoxia or hypercapnia. Increased physiological arousal, in turn, exacerbates anxiety symptoms, which then produce greater physiological insufficiency, resulting in a self-perpetuating cycle of dyspnea and panic.

### **Cognitive Functioning**

Studies have documented mild impairment in neuropsychological functioning among patients with

COPD. Impairments have been observed in problem solving, psychomotor speed, attention, and verbal memory, but verbal intelligence does not appear to be affected. Studies suggest that there is a modest correlation between neuropsychological impairment and hypoxemia, but that neuropsychological functioning is not associated with standard indicators of pulmonary function.

### **Social Functioning**

The physical limitations of COPD may have profound effects on family relations and lifestyle, including diminished wage-earning ability, changes in family roles, reduced independence, reduced social activities, and impaired sexual functioning. Perceived social support and satisfaction with social resources have been found to influence functional status both directly and indirectly (via negative mood and somatic symptoms).

### **Behavioral Functioning**

Patients with COPD are typically confronted with difficulties in numerous areas of life functioning and may report significant impairments in bathing, grooming, dressing, eating, sleeping, and mobility. In addition to difficulties in ambulation and home management, COPD often limits recreational activities. No direct relationship between pulmonary function and functional status has been observed, but pulmonary function may indirectly affect functional status via its effect on exercise capacity. In general, pulmonary function appears to be no more important in predicting functional capacity than other more subjective factors, including indicators of psychological well-being.

### *Medication Compliance*

The medical regimen of individuals with COPD is often complex, with an average of 6.3 medications per patient. Consequently, nonadherence is high, with about half of patients overutilizing or underutilizing their medications. Unfortunately, little is known about the factors associated with noncompliance in patients with COPD or about ways in which compliance can be increased in this population. The most common reasons for noncompliance among patients with COPD are forgetfulness and refusal to take medications,

both of which are thought to result from patients feeling well enough without medication. Other factors frequently associated with noncompliance are medication side effects, changes in daily routines, running out of medication, and impaired long-term memory.

### *Treatment Strategies*

Because of the independent influence of emotional and behavioral factors on daily functioning, treatments designed to increase physical health and quality of life among patients with COPD must focus on reducing emotional distress and modifying maladaptive behavior patterns. Psychological distress may be treated by means of group counseling, psychotherapy, medication, exercise rehabilitation, or a combination of several modalities. Psychological treatments targeting catastrophic misinterpretations of bodily symptoms are thought to decrease experiences of panic in COPD patients. Relaxation training also may reduce symptoms of anxiety, dyspnea, and airway tightness in COPD patients.

One prototype for treatment of pulmonary patients is the cognitive-behavioral format in which patients are taught relaxation skills, combined with cognitive restructuring and identification of emotional changes. This approach, in either a group or individual format, provides patients a model for coping with situations that trigger psychological distress and physical symptoms. Activity planning and pacing are essential in the treatment of patients with COPD, and may be included in cognitive-behavioral interventions. Patients are encouraged to schedule daily activities, list them on a daily planner, and mark them off as they are completed. This approach has been shown to contribute to significant increases in walking activity among patients with COPD and to facilitate compliance with medical care recommendations (e.g., medications, exercise). Scheduling pleasurable activities is encouraged to facilitate the patient's sense of control and to prevent depressive symptoms. Patients also learn to adapt to the slower pace at which they complete physical activities and to identify enjoyable aspects of their daily activities. Although cognitive-behavioral treatments usually occur in four or more sessions over the course of several weeks, recent data have demonstrated the efficacy of a brief (2-hour) group session of cognitive-behavioral treatment for reducing depression and anxiety among patients with COPD.

Due to the importance of social support for health and psychological well-being of patients with pulmonary disease, pulmonary rehabilitation programs provide an ideal way for patients to meet with their peers, to learn about their illness, and to learn strategies for minimizing their symptoms and increasing their physical endurance. Rehabilitation programs may include spouses/caregivers in the educational components of the program to facilitate adherence to medical care recommendations after the rehabilitation program has been completed and to provide a forum for discussion of changing roles/responsibilities in the home environment.

### *Smoking Cessation*

For most patients, symptoms of COPD or a recent diagnosis with COPD are sufficient to motivate smoking cessation. However, for patients who continue to smoke, behavioral research suggests that comprehensive treatments targeting psychological functioning may increase the efficacy of smoking cessation, and that a multicomponent treatment program may be more effective than treatment in a single modality. In addition, psychological variables seem to play a role in both the ability to quit smoking and the likelihood of relapse. Self-efficacy expectations are the strongest predictor of smoking cessation among patients with COPD, and depressed mood has been associated with reduced ability to quit smoking. Thus, smoking cessation interventions in this population are most likely to succeed by targeting self-efficacy expectations and depressed mood.

### *Nutritional Status*

Studies indicate that a significant number of patients with COPD are malnourished, as indicated by lower than normal body weight, tricep muscle skin folds, arm muscle circumference, and caloric intake. Recent behavioral research has indicated that malnourishment may be associated with impaired psychological well-being and that dietary supplements may reverse deterioration in both psychological and physical functioning associated with depleted nutrition.

### *Physical Exercise*

Exercise among patients with COPD generally is associated with reductions in depression and anxiety,

increased positive affect, and increased self-efficacy for walking. Exercise also has been associated with enhanced quality of life and with improvement in aspects of cognitive functioning (e.g., verbal fluency, psychomotor performance). Exercise compliance is at the heart of all rehabilitation programs, and continued compliance (adherence) is essential for patients to maintain gains following the program. The relapse prevention strategy appears to be useful for patients with COPD in that it teaches patients to prepare for and respond to bouts of illness, during which they may be temporarily reluctant or unable to exercise. In addition, because negative mood states may be associated with reduced energy and diminished interest in activities such as exercise, strategies for improving mood also, in turn, are likely to contribute to better exercise performance. Ongoing studies have evaluated procedures to encourage individual, in-home exercise behavior, and recent data suggest the effectiveness of strategies such as distractive auditory stimuli (e.g., music) for enhancing exercise performance among patients with COPD.

## SUMMARY

Psychosocial effects of COPD include psychological distress, cognitive impairment, and reduced ADLs. Exercise training has a positive effect on all three areas of functioning. In addition, cognitive-behavioral strategies have proven useful in treating patients with significant mood disturbance and other behaviorally based problems, including continued cigarette smoking, poor eating habits, and noncompliance with exercise or other medical recommendations.

# CHRONIC PAIN MANAGEMENT

Medical advances and interventions have yielded significant gains in life expectancy, but the increasing prevalence of pain complaints threatens to impair quality of life. Appropriate pain assessment and management present significant challenges for patients, health care providers, health care organizations, insurance providers, and health care policymakers. This entry provides an overview on chronic pain assessment and management.

## INTRODUCTION

Pain involves damage to the body (e.g., twisting an ankle, burning a finger), communication that there is an injury from the site of the injury to the spinal cord (i.e., transmission), and last, communicating this information from the spinal cord to the brain where pain is perceived (i.e., perception). In addition, there is often an emotional response to pain. Pain is defined as an "unpleasant sensory and emotional experience associated with actual or potential tissue damage." This definition involves perception of a painful stimulus and reaction to the sensation, which includes a level of subjectivity to the pain experience. Thus, it follows that pain significantly affects overall health (i.e., a state of complete physical, mental, and social well-being). This definition for pain entails a broader concept than that typically employed in biomedical research and clinical medicine, transcending both physical disease and emotional distress.

In general, pain is described by a simple relationship to an inciting event or injury, which is generally protective and self-limited, especially in the acute (early) injury phase. Although most often a protective

**Figure 1** Consequences of Chronic Pain

phenomenon, pain can be detrimental, increasing morbidity (i.e., increasing heart rate and blood pressure, causing fear and anxiety). There is considerable overlap in the types of pain, although it is most often classified by duration or etiology as (1) acute (i.e., pain of less than 6 months duration), (2) chronic (aka, chronic nonmalignant pain, chronic benign pain; i.e., pain of greater than 6 months duration), or (3) cancer pain (i.e., pain that is attributed to cancer or is the sequelae of cancer treatment).

### IMPACT OF PAIN

Chronic pain is estimated to be the third largest health problem in the world. It is also a national health problem with significant implications on health and wellness. The increasing prevalence of chronic pain has significant and potentially devastating socioeconomic and health ramifications. For instance, pain affects more than 75 million Americans. More specifically, back pain is estimated to be the leading cause of chronic pain and the second leading cause of all physician visits. Pain leads to more than 700 million lost workdays and greater than \$60 billion in health care expenditures annually. Americans spend an additional \$40 billion a year on chronic pain. Chronic pain is the most frequent cause of disability in the United States.

Chronic pain affects many facets of an individual's life. Beyond the physical manifestations, there are significant suffering and psychological manifestations due to chronic pain. When compared to the general population, patients with pain have an increased psychological burden, as demonstrated by the high prevalence of posttraumatic stress disorder (PTSD), sleep disturbance, anxiety, and depressive symptoms, which independently increase morbidity and mortality. Pain does not occur in isolation and has a significant impact on the caregiver. In many chronic medical conditions, social health support systems diminish. Thus, lower social supports from caregivers and family members of

people living with chronic pain are important factors that may have an additive effect in increasing an individual's risk for psychological distress and suffering due to pain. The potential ways that chronic pain affects an individual's health are shown in Figure 1, which illustrates how pain impairs physical, psychological, social, and economic functioning.

Despite the significant toll of chronic pain, there are no universal guidelines for chronic pain management. The U.S. Agency for Health Care Policy and Research (AHCPR) sponsored the development of guidelines for the treatment of acute postoperative and cancer pain as well as for chronic low back pain. Yet 70% of cancer patients die with uncontrolled pain, and nearly 40% of postoperative patients experience significant pain. This has profound effects on outcome (e.g., increased morbidity and mortality), quality of life, and health care expenditures. Clearly, as Americans live longer, the prevalence of pain will increase, impairing quality of life as well as health and well-being. Yet all types of pain remain relatively undertreated, and the adequate assessment and appropriate management of chronic pain remain a neglected part of medicine. To complicate things further, most physicians have received minimal pain education, although there are many different modalities available to treat patients with pain.

### DIFFERENCES IN CLINICAL PAIN

The effects of pain vary substantially. For example, two patients with the same level of disease activity can differ greatly in terms of the amount of pain that they report and its impact on their lives. Little is known about how gender, aging, and ethnicity influence the effective provision of pain management. Biological, physiological, and sociological mechanisms have been proposed to explain the differences in the pain experience. These mechanisms include differences in the reproductive organs, sex hormones, central nervous system, pain-learning methods,

culturally imposed factors, and social roles that predispose certain individuals toward increased responsiveness to a painful stimulus. How these differences apply to the individual with pain remains unknown.

The literature indicates definite gender differences in the prevalence of many chronic pain conditions. Although prevalence patterns may vary by stage in the life cycle, women have a higher overall prevalence for most chronic pain conditions. Certain clinical pain conditions (e.g., fibromyalgia, temporomandibular joint disease, tension-type headache) that are unrelated to the gynecologic organs are much more prevalent in women. These chronic pain syndromes are often characterized by increased experimental pain sensitivity and enhanced vulnerability to experimental pain, suggesting gender-based differences in pain modulation. Gender-based differences in pain symptoms for both acutely and chronically painful conditions as well as response to opioid analgesics have been reported. The clinical implications of these unique gender-related findings for pain management in a chronic pain population are unclear.

## MANIFESTATIONS OF PAIN

Differences in the ability to cope with pain have been identified. Availability and satisfaction with social support are important factors to consider in adaptation to any chronic illness such as chronic pain. An abuse history has been shown to affect chronic pain symptoms and coping. For instance, chronic physical or sexual abuse history (i.e., sexual or physical abuse that occurred during both adulthood and childhood) might be an important predictor for the development and maintenance of chronic pain states in women. In addition, patient attitudinal differences in regard to pain may influence the chronic pain experience. Limited awareness of the impact of chronic pain and the scarcity of outcome studies may increase the likelihood of the undertreatment of pain.

Variability in treatment based on gender can lead to differences in outcome. The literature suggests that physicians handle the pain complaints of women, racial and ethnic minorities, and the elderly less aggressively. The gender of the physician has also been shown to contribute to variability in the treatment women receive for pain. Differences in the way women communicate their pain concerns may increase the likelihood of their complaints being attributed to a mental health disorder.

Disturbing differences exist in the treatment of pain based on the patient's age, race, and gender, with women and ethnic minorities receiving lesser-quality care. However, little is known about how patient demographic and cultural factors influence pain treatment-seeking behavior and treatment. Considerable physician variability in the treatment of pain has been demonstrated, revealing lesser goals for chronic pain relief, less satisfaction in the management of chronic pain, lesser treatment for women with pain, and decreased ability to manage chronic pain versus other types of pain. Physician variability and suboptimal treatment strategies for chronic pain may lead to increased suffering while adversely affecting an individual's overall health.

To address the inadequate treatment of pain, many specialty organizations have developed guidelines for pain assessment and management. In addition, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) developed pain requirements for all accredited organizations. The requirements are as follows:

1. Recognize the rights of patients to appropriate assessment and management of pain.
2. Assess the existence of and the nature and intensity in all patients.
3. Record the results of the pain assessment in a way that facilitates regular assessment and follow-up.
4. Determine and ensure staff competency in pain assessment and management in the orientation of all new staff.
5. Establish policies and procedures that support the appropriate prescription or ordering of effective medications.
6. Educate patients and their families about effective pain management.
7. Address patient needs for symptom management in the discharge processes.

## PAIN ASSESSMENT

Pain is a subjective personal experience with no objective measures. Models used to determine pain perception in the experimental research setting do not transfer well to the clinical arena. Thus, pain perception is subjective and personal. Each patient reacts to

a painful stimulus and the pain experience differently. Initial pain assessment requires a thorough history and physical exam.

The gold standard for pain assessment remains patient self-report. On initial assessment, health care providers should assess the patient for pain. Most commonly, the assessment of pain entails asking the patient to quantify his or her pain via a 10-point visual, numerical, or verbal analog pain scale (0 = *no pain*; 10 = *worst pain*). Another important component in quantifying pain involves assessing how comfortable and how satisfied patients are with their level of pain. A patient with a pain score of 7 (typically consistent with severe pain) may be completely comfortable and satisfied with his or her pain regimen while another patient may report a pain score of 3 (typically consistent with mild pain) and be uncomfortable as well as unsatisfied with the pain control. It is important to note that quantitative pain estimates from surrogates should not be used unless the patient is unable to report.

Other scales can be helpful in assessing pain depending on the patient's vision, cognition, and development. Both geriatric and pediatric patients as well as persons who are cognitively or visually impaired, non-English speaking, and racial and ethnic minorities may have trouble with using traditional methods to assess their pain. These communication challenges put certain populations at risk for the undertreatment of pain. Different scales have been developed and are available to address those with special needs and disabilities. For instance, elderly people may prefer to use word descriptors (e.g., "none," "mild," "moderate," "severe," "extreme") to quantify their pain, while children may prefer visual cues (e.g., faces). Of particular importance is that elderly people often minimize the impact of pain on their lives and may not use the word *pain*. Furthermore, they may view pain as a normal part of aging that they must learn to live with. Children may not be able to quantify their level of pain due to their level of development and may prefer to choose faces or to use colors to describe their pain. In addition, parental assessment of the child's behavior may be necessary.

A physician should assess persistent pain that significantly affects function or quality of life. Information regarding pain characteristics (e.g., burning, aching, soreness) is sought. Reports from family members and caregivers are often helpful in assessing pain. The comprehensive assessment of pain as done

in pain centers often involves a pain diagram and an evaluation of psychosocial function. This often includes the completion of lengthy surveys (e.g., McGill Pain Questionnaire, West Haven Yale Multidimensional Pain Inventory) and pain diagrams. Mood assessment, especially depression (e.g., Beck Depression Inventory), as well as sleep disturbance, disability (Pain Disability Index), and social support relationships, are also done. Evaluations of physical functioning and limitations are also part of the exam.

Considerable misinformation regarding pain management exists. Physicians have received minimal education regarding pain and do not routinely ask about the presence of pain, yet it is one of the most common reasons that a patient consults a physician. Regulatory policies surrounding opioid analgesics may limit their prescriptions for pain management. Furthermore, insurance issues may also limit access to certain types of pain treatment. It is critically important for patients and their physicians to become partners in developing a treatment plan designed to improve the patient's quality of life. Thus, as partners in their own pain care, it is important that patients present their pain complaints to their physicians. It is extremely important and helpful if patients bring a notebook to the doctor appointments with questions and concerns regarding their pain.

#### **Recommendations for Patients With Persistent Pain: How to Discuss Pain Complaints With Health Care Providers**

1. Know your pain rights. Make certain that your health care provider is aware of your pain.
2. Describe the circumstances or events that led to the pain as well as the duration of pain.
3. Describe where the pain is located as well as its character, frequency (or pattern), and location.
4. Describe if the character or quality of your pain has changed.
5. Describe how bad the pain is (e.g., 0 = *no pain*, 10 = *worst pain imaginable*) today, on a good day and on a bad day.
6. Describe any precipitating and relieving factors (i.e., what makes it worse and what makes it better).
7. Describe any associated symptoms.
8. Describe how the pain has affected your life (i.e., sleep disturbance, weight gain or loss, eating changes, depressive symptoms, marital discord, alcohol and cigarette use).

9. Discuss any previous pain problems and any family history of pain problems.
10. Discuss current and previously used therapeutic modalities including prescription and nonprescription analgesics, over-the-counter medications, and nonpharmacological approaches. Note the effectiveness and side effects of each therapeutic modality.
11. Keep a pain journal or log with regular entries that include time the pain occurred, pain intensity and severity, medication(s) used, and how your pain responded.

After initial assessment (including physical exam) and determining the cause of pain, both the patient's and the physician's goals for pain relief should be established and agreed on. A treatment plan should be developed, since inadequately treated pain can lead to significant health problems (e.g., sleep problems, depression, anxiety, social isolation, health care utilization) while exacerbating other medical problems.

## TREATMENT FOR PAIN

### Therapeutic Modalities

The initial treatment plan involves obtaining a complete history and physical examination, review of laboratory and other tests, and documentation of pain. Since pain involves perception, transmission, and the initial injury, therapeutic agents work at many different levels.

### Education

Education is an important step in treating pain. As a first step, information on the impact of pain on the individual, family, and society should be provided or obtained, since many things affect pain. In addition, education about different therapeutic modalities should be provided for patients, caregivers, and family members; health care providers; and health care policymakers.

### Nonopioid Analgesics

*Acetaminophen* is a first-line drug and the drug of choice in relieving mild to moderate pain, especially musculoskeletal and arthritis pain. It is often used as a combination product with other analgesics. Since

toxic levels can occur, doses should be limited to less than 4,000 mg/day in adults or less than the 3,000 mg/day in the elderly. It does not inhibit wound healing and can only be administered orally or via the rectum.

*Nonsteroidal anti-inflammatory drugs (NSAIDs)* are commonly used to provide analgesia. NSAIDs work at multiple places, including the brain, to provide analgesia. They primarily inhibit prostaglandins, which are produced by COX-1 and COX-2 enzymes by inflamed tissues in response to pain. Although NSAIDs are very effective analgesics, they have significant side effects and are the most common cause of adverse drug reactions (e.g., gastrointestinal bleeding, nausea, kidney problems), especially in the elderly. The traditional NSAIDs, which inhibit the COX-1 enzyme (e.g., ibuprofen, naproxen), may cause more gastrointestinal injury than the newer agents, which specifically inhibit the COX-2 enzyme (e.g., rofecoxib, celecoxib). When used with opioid analgesics, they can decrease the opioid analgesic requirements. However, NSAIDs should be stopped several days prior to surgery.

*Aspirin* is a common anti-inflammatory agent. However, it is of limited use in the chronic pain setting due to its many undesirable side effects (e.g., bleeding, bruising). Aspirin should be stopped prior to surgery.

### Opioid Analgesics

Opioid analgesics (aka, narcotic analgesics) are the most common modality used for acute postoperative pain and are primarily used for moderate to severe pain problems in carefully selected patients with chronic pain. They are powerful analgesics (pain relievers), which primarily work in the spinal cord, brain stem, brain, and peripheral tissues to prevent the release of substances that cause pain. The opioid analgesics (e.g., morphine, hydromorphone, codeine, oxycodone, hydrocodone, methadone, and fentanyl) most commonly used provide significant analgesia via many different routes (i.e., oral, spinal, nasal, intravenous). However, opioids are often associated with undesirable side effects (e.g., constipation, respiratory depression, sedation, dependence, nausea, and vomiting). When prescribed, it is not unusual for the patient and physician to sign a contract describing conditions for their use, since they are often regulated.

## Adjuvants

### *Antidepressants*

The classical and most studied antidepressants, the tricyclic antidepressants (e.g., amitriptyline, nortriptyline, desipramine, and venlafaxine), have proven efficacy but also have more side effects than selective serotonin reuptake inhibitors (e.g., fluoxetine, sertraline, paroxetine) alone and in conjunction with other therapeutic modalities. Antidepressants have proven efficacy in the management of chronic pain (e.g., central poststroke pain, migraine and tension headache), especially neuropathic (nerve) pain (e.g., diabetic neuropathy, postherpetic neuralgia), and may decrease sleep disturbance. Chronic pain relief may occur without an antidepressant response, since their analgesic action is not mediated by the agent's antidepressant activity. In fact, antidepressants bind weakly at the same site as opioids do. The analgesic activity is more rapid (3-7 days) than when used for their antidepressant activity (14-21 days). They primarily work to improve sleep and pain by increasing the levels of certain hormones in the spinal cord, brain stem, and thalamus (e.g., dopamine, norepinephrine, and serotonin) acutely and chronically by regulating receptors and the activity of these hormones.

### *Other Adjuvants*

Other adjuvant therapies have proven themselves to be extremely useful for pain problems. Antiepileptic medications (e.g., gabapentin, valproic acid) are commonly used to treat painful neuropathies (e.g., radicular back pain, trigeminal neuralgia). In addition, commercially available local anesthetics impregnated in gauze (e.g., 5% lidocaine) and oral local anesthetics (e.g., mexilitene) have been useful in treating postherpetic neuralgia. Medications used to treat spasm often assist in treating pain (e.g., tizanidine, baclofen).

## Complementary and Alternative Techniques

Simple comfort measures (e.g., ice, heat, massage, prayer, reassurance) have been used for generations to enhance analgesics and should be used as potential modalities to control all types of pain. Complementary and alternative techniques (e.g., distraction methods, exercise, relaxation techniques, and music therapy) are very popular and are being increasingly researched. For instance, acupuncture and acupressure

have been used to decrease pain as well as the common side effects of traditional analgesics. Herbal medications (e.g., glucosamine chondroitin) are also beneficial in treating arthritic conditions. Nonpharmacological approaches (e.g., transcutaneous electrical nerve stimulation; TENS), used alone or in combination with appropriate pharmacological techniques, can be beneficial.

Chronic pain support groups are helpful as a mechanism for patients to improve their pain control. They allow patients to share their pain experiences while taking an active role in their recovery.

## Nerve Blocks

Therapeutic nerve blocks (e.g., epidurals) are often used to provide anesthesia (using local anesthetics) for surgical procedures. Pain management specialists use nerve blocks in selected patients. They are most often used when the pain follows an anatomic distribution or when anesthetic techniques can be used. These highly specialized therapies are particularly helpful for cancer pain syndromes and disorders involving the sympathetic nervous system (e.g., acute herpes zoster, reflex sympathetic dystrophy). Nerve blocks are most successful when used in conjunction with other therapeutic modalities.

## Manual Therapy

Physical therapy provides significant benefit for musculoskeletal problems to reduce pain and improve function. In addition, patients may benefit from aqua therapy to reduce stress in painful joints. Physical therapists with expertise in treating patients with chronic pain are desirable. Patients benefit the most when they are actively engaged in their care by participating in a structured program, both at an outpatient facility and in their home.

## Psychological Counseling

Patients often have a psychological reaction and experience poor coping due to chronic pain. In general, maladaptive coping (e.g., *catastrophizing*, repression) and poor adjustment (e.g., poor information seeking, passivity) appear to be important contributors to diminished health. Cognitive and insight-oriented psychotherapy is often warranted and provides significant benefits. Those patients who are

addicted to or abusing any legal (e.g., alcohol, cigarettes) or illicit substances should be referred to experts in pain, addiction, and psychiatry. The major reason pain does not get better is the failure to realize that psychological component. By recognizing the impact of emotions, people living with chronic pain can reduce stress, enhance coping, and decrease the impact of pain.

Repeat assessments with the same tools used during the initial pain assessment should be done. Included in these repeat assessments is a review of goals as well as medications and side effects due to therapies.

## REFERRAL

When, despite efforts to treat pain, the patient's or the physician's pain relief goals have not been met, referral to a multidisciplinary pain center for evaluation and treatment should be considered. The most successful treatment usually involves multiple approaches directed at treating the different components of pain via multiple modalities. Seemingly small changes in combination with multiple therapeutic modalities can often lead to significant improvement in a patient's pain and quality of life. The following provides information on how treatment modalities might progress:

1. Nonopioid  $\pm$  adjuvant
2. Opioid for mild to moderate pain + nonopioid  $\pm$  adjuvant
3. Opioid for mild to severe pain  $\pm$  adjuvant

Although chronic pain causes significant disability, an understanding of the treatment modalities available leads to healthier lifestyles, improved quality of life, and enhanced outcomes.

## CHURCH-BASED INTERVENTIONS

Throughout history, physical health has been a common component of the philosophy and the activities of religious organizations (ROs). However, as modern medicine emerged and intensive training and technology became the norm for the provider, medicine assumed more responsibility for physical health and ROs concentrated more on spiritual health. ROs did not ignore physical health, but their primary emphasis was on helping people with diseases to cope, rather than on disease prevention. As medicine continued to become more of a profession, the emphasis in ROs expanded to employing providers (e.g., parish nurses) or utilizing the RO facility as a clinic for medical care delivery.

As public health shifted from a focus on behaviors related to infectious diseases (e.g., sanitation, immunizations) to a broader view of health-related lifestyle factors and prevention of chronic diseases, funding agencies such as the National Institutes of Health began to include more funding for behavior change programs. Medical researchers began to partner more with behavioral scientists. In the mid- to late twentieth century, behavioral medicine researchers began to look to partner with various community organizations (e.g., work sites, schools) for program delivery as they searched for wider impact and recognized that many of these lifestyle behaviors are developed and maintained in the community. While ROs were included as partners in health care delivery, the programs implemented were rarely empirically evaluated and program development was not usually driven by behavior theory. This was due largely to the fact that most larger scale behavioral medicine research was federally funded. Fear of crossing the line of separation of church and state was a deterrent to both applying for and/or dispensing federal research funds for partnerships with ROs. Even private foundations shared this hesitancy. This resistance began to break down in the

1970s and 1980s with an accelerating interest in funding and in conducting such efforts. Thus, studies in ROs that include theory-driven behavior change interventions evaluated by sophisticated research designs are a relatively new phenomenon.

There are many advantages (and some disadvantages) for researchers, ROs leaders, and congregations to become involved in research partnerships for studying behavior change interventions. For researchers interested in large-scale public health programming, ROs provide a channel with enormous reach. The 2002 edition of the *Yearbook of American and Canadian Churches* reports over 152 million members of those ROs in the United States that report figures. Since nonmembers often attend health events at ROs, a large majority of U.S. citizens are reachable through programming in partnership with ROs. In addition, RO facilities are everywhere. Along with fire stations and schools, ROs are generally permitted in all neighborhoods regardless of zoning restrictions. In addition to availability, the designs of RO facilities are compatible with education. For example, classrooms are often an integral part of their design. Also, ROs are viewed as places where teaching and learning are expected, unlike other sectors such as retail and work sites.

Furthermore, ROs provide access to minority populations. This allows involvement of these participants (who are often hard for academic researchers to reach) in a safe and trusted environment. The RO is often the primary community organization, especially in African American neighborhoods, and are very influential in Hispanic neighborhoods as well. ROs also have relatively stable memberships with individuals who change residences often while still remaining members of the same RO. This is particularly important when the study is longitudinal and retention of participants for follow-up evaluations is critical. In addition, ROs are the only large-scale organization that includes the entire family over many years. Other critically important social networks also may be accessed through the RO. These networks can be utilized and built upon to help achieve and sustain behavior changes that affect others as well as the participant (e.g., changes in nutrition and physical activity, weight loss/control, smoking cessation). Volunteerism in ROs is the norm, with many aspects of the organization staffed by volunteers. Such volunteers bring more than inexpensive labor. They are members of the social networks of interest in lifestyle

change programs, thus providing ready access. Also, volunteers are already accepted by potential participants, understand the cultural context within which the changes are to take place, and speak the language of the participants. Furthermore, volunteers provide “coping models” as they make lifestyle changes themselves and remain as a resource long after funding for the research ends. They are also invaluable in recruitment and retention of formal research samples of participants. Finally, volunteers are more likely to be in a position to make appropriate environmental (physical and social) changes in the RO organization and facility (e.g., establishing health committees, healthier “church suppers,” no-smoking policies).

While there are many advantages for research partnerships, disadvantages must also be recognized. The academic research culture and that of ROs are quite different. For example, the RO culture tends to emphasize inclusiveness, but research designs often require withholding of the intervention to some for comparison purposes. Random assignment must also be thoroughly explained and justified to RO leaders and congregations. At least one investigator found that the pastors she worked with would not accept this traditional research design requirement. Another disadvantage revolves around the mandatory support of the RO leader, who can sometimes change during a study. RO leaders are very busy, so requiring much of their time will greatly reduce the number of ROs that will participate in the study. Thus, many researchers rely upon a key layperson or, in larger ROs, a “health” cleric as the primary liaison with the leading cleric. Another potential disadvantage for the researcher is the time required to establish meaningful partnerships and to sustain the relationships over time and across cleric changes.

Advantages for the RO leaders to be involved in research partnerships include the opportunity to provide their congregations with access to new health programs—this is especially true for ROs with large numbers of underserved members. The health programming also provides a venue for attracting new members. The disadvantages for the RO leaders include potential strain on the limited RO physical and financial resources, placing further demands on extremely busy clerics, and distraction of potential volunteers from other committees and activities more directly linked to the RO’s main mission. Some topics may also be in conflict with existing RO teachings (e.g., contraceptive use). Finally, the program being

provided by the research project may quickly disappear once research funding is over, leaving both the congregation and leadership feeling used and discarded.

This entry reviews behavior change research studies that have been conducted in ROs. Only studies including randomization, a longitudinal design, a comparison (or control) group, and evaluation of the physiological and/or behavior changes targeted by the intervention are included in this discussion. A number of other studies that did not involve random assignment and/or a comparison group indicate the versatility of ROs for behavior change research partnerships, and may be helpful references for the reader interested in feasibility issues. These studies have been conducted in a number of areas including cardiovascular health, weight loss, aerobic exercise, cholesterol control, nutrition change, fruit and vegetable increase, and cancer screening. The projects for inclusion in this discussion are also further restricted to those targeting specific and measurable outcomes rather than only process and feasibility variables such as acceptability and attendance. No attempt was made to include the broader topics of religion and health care delivery and the relationships between religion and mental and physical health. Other reviews can be found elsewhere.

The research studies that met our criteria, included in Table 1, are classified by level of involvement of the RO according to the definitions proposed by Lasater et al. Studies at Level I simply utilize ROs as sources of recruitment for a behavior change program. The Harlem Health Connection was a self-help smoking cessation project with recruitment for smoking cessation taking place in ROs, health care sites, and public housing projects. The self-help cessation program did not yield statistically significant effects compared to a no-treatment control. However, the church participants were the most likely to give a phone number and yielded the highest percentages of completed intervention phone calls compared to the health sites and public housing developments. Level II adds use of the RO facilities for delivery of at least some of the behavior change interventions being tested. The three studies reviewed for this level have reported positive results, but these are primarily attributable to the interventions themselves and not to the partnership with ROs, as only the RO facilities and target populations (congregation) are used.

Level III projects include members of treatment ROs as an important component of program delivery.

**Table 1** Representative Studies by Level of Partnership

<i>Level</i>	<i>Project Name</i>	<i>Topic</i>	<i>Ethnicity/Race<sup>a</sup></i>	<i>Target</i>	<i>Unit of Assignment</i>
I	Harlem Health Connection	Smoking Cessation	AA	Sample	133 Smokers
II <sup>b</sup>	Eat for Life	Fruit and Vegetable Consumption	AA	Sample	14 ROs
II <sup>b</sup>	Healthy Body/Healthy Spirit	Fruit and Vegetable Consumption	AA	Sample	16 ROs
II	Minimal Contact Education for Cholesterol Change	Cholesterol-Lowering Diet	H, NHW, AA	Sample	36 ROs
III	Campañeros el la Salud	Cancer Prevention and Control	H	Congregation	14 ROs
III	Go Girls	Weight Control for Adolescent Females	AA	Sample	10-14 middle and upper SES ROs
III	North Carolina Black Churches United for Better Health	Fruit and Vegetable Consumption	AA	Counties	50 ROs
III	PRAISE!	Cancer Nutrition	AA	Congregation	60 ROs
III	HARP	Cardiovascular risk factors	NHW	Congregation	25 ROs
III	LAMP	Mammograms	H, NHW, AA	Sample	45 ROs
IV	Project Joy	Cardiovascular risk profiles	AA	Sample	16 ROs
IV	Heart, Body and Soul	Smoking Cessation	AA	Sample	22 ROs
IV	LIGHT Way	Nutrition and Physical Activity	AA	Sample	26 ROs
IV	SisterTalk Hartford	Weight Control	AA	Sample	12 ROs
IV	Pacific Rim Cancer Screening Awareness Through Churches	Mammograms	H, NHW, AA, A	Sample	78 ROs

<sup>a</sup> H = Hispanic; NHW = Non-Hispanic White; AA = African American; A = Asian

<sup>b</sup> Intervention includes scriptural elements.

At this level, the partnership is able to add volunteers for many of the program logistics, including program delivery. It is also easier to ensure that more of the elements of the intervention are consistent with those of the target audience. This is particularly important when tailoring interventions for specific cultural groups. Resnicow et al. state that culturally sensitive interventions can be conceptualized by two primary dimensions: surface structure and deep structure. Surface structure involves matching intervention materials and messages (channels and settings, people,

places, language, music, food, brand names, locations, and clothing) to observable social and behavioral characteristics of a target population. Deep structure involves how populations differ in general (i.e., core cultural values), as well as how ethnic, cultural, social, environmental, and historical factors may influence specific health behaviors. Level III interventions are more able to be culturally tailored, as church members and volunteers are more involved in program design and delivery. In addition, at Level III, the results reported can more comfortably be attributed, at least

in part, to the partnership and not just the behavioral intervention alone. Only one of the six Level III studies has reported final results. Campbell et al. reported very impressive changes in fruit and vegetable intake.

Level IV adds spiritual/scriptural components to the interventions that include congregation members in the delivery of the program. Spirituality is a core cultural value for many populations groups, including African Americans and some Hispanic groups. Inclusion of spiritual/scriptural components allows for a better fit between program and participants (deep structure), can maximize motivation, and should increase the length of time the program is maintained after funding ends. At this level, the full benefits of the partnership can be realized. Intervention designers can incorporate elements from both behavioral theory/practice and the motivating and supportive underpinnings of the religious teaching. Five studies have been classified as Level IV. There have been several projects that included scriptural elements, but were not delivered by RO members. Thus, they remained classified as Level II.

Several Level IV studies have published study results. Project Joy has reported positive results for weight and some dietary intake variables. The other Johns Hopkins University study, Heart, Body and Soul, also reported positive impact on progress along stages of change in smoking behavior. The other studies at Level IV have not yet published final results, but early indications are very positive for feasibility and for the compatibility of faith-based teachings and behavior change theory and practice. With the exception of the Pacific Rim Cancer Screening Awareness through Churches study by Sarah Fox at the University of California, Los Angeles, all the Level IV studies to date have been (or are being) conducted primarily with African Americans. More Level IV studies with other ethnic groups are needed.

Thus, there have been a number of large, scientifically sound RO-based behavioral intervention studies funded in the past several decades, with the majority being funded in the past 10 years. It is feasible to conduct behavioral medicine research in partnership with ROs. Most of the lessons learned to date tend to be how to form and sustain the partnerships. In addition, those programs that have relied upon volunteers from within the RO as program implementers have found that such volunteers are available in sufficient numbers and can be trained to effectively deliver lifestyle behavior change programs in their own ROs.

Almost all of the current studies have been conducted with churches. Whether the establishment of

such research partnerships can be extended to other ROs such as synagogues and mosques remains to be determined, and should be studied. Although few final results are available in the literature, it is clear that positive behavior change can be achieved in RO-research partnerships. More research needs to be done before generalizable conclusions can be made about conducting behavior change research in ROs compared to other types of community organizations.

## COGNITIVE FUNCTION AND HEALTH

---

It is well known that neurological (brain) diseases such as Alzheimer's disease can have a devastating

impact on cognitive abilities, frequently causing serious disabling mental impairment known as dementia. Recently, we have learned that medical diseases involving physiological systems other than the brain, such as the cardiovascular (heart and blood vessels), pulmonary (lungs), and hepatic (liver) systems, can also negatively impact cognitive function by exerting a variety of direct and indirect effects on the brain. Furthermore, factors that influence the development of medical diseases, such as health habits and hormones, and treatments for disease can also affect the brain and cognitive function by both direct and indirect means. Overall, it seems that healthy people tend to have better cognitive function whereas unhealthy people tend to have poorer cognitive function.

What is cognitive function? It refers to one's ability to perceive, process, and respond to information and includes a variety of skills such as attention, learning and memory, the ability to organize and execute purposeful behavior (i.e., executive functions), spatial and perceptual abilities, speed of processing and responding to information, and language abilities. Having adequate cognitive function is an important aspect of people's quality of life. When individuals experience cognitive difficulties, it can diminish their sense of well-being and sometimes their ability to function in their everyday lives.

As people get older, they typically experience some decline in cognitive function. It is thought that at least a portion of this cognitive change that has previously been attributed to the aging process is actually due to medical diseases that are common in older adults. Important, though, is the finding that medical diseases (and other biological and lifestyle factors that promote illness) can negatively affect the brain and therefore cognitive function in people of any age, and may exert cumulative effects over time. Similarly, certain good health habits can help protect cognitive function at any age.

Examples of the types of factors related to health and illness that can affect cognitive function include lifestyle factors, hormones, genetics, medical diseases, exposure to toxic substances in the environment, and medical and surgical treatments for disease (see Waldstein, 2000). These factors typically do not disable the brain and associated cognitive abilities to the same extent as do the neurological diseases such as Alzheimer's disease. However, even the more mild to moderate effects of these factors on cognitive

function can impact people's lives and can predispose to more serious impairments further on down the road if the diseases are not treated properly.

Several lifestyle factors or health habits are known to affect cognitive function. For example, health-compromising behaviors such as smoking, heavy alcohol consumption, drugs of abuse (e.g., opiates, cocaine), and physical inactivity have been associated with poorer cognitive function. In addition, dietary insufficiencies, such as vitamin B<sub>6</sub>, vitamin B<sub>12</sub>, thiamine, folate, and zinc, have been related to cognitive difficulties, as has high caloric consumption. In contrast, health-enhancing behaviors have been associated with better cognitive functioning. For example, greater intake of antioxidants such as vitamin C and greater levels of physical fitness or physical activity have been associated with higher levels of cognitive function. In addition, cognitive function can improve with aerobic exercise training in both healthy people and people with chronic medical diseases. For example, Dr. Charles F. Emery and his colleagues at Ohio State University found that patients with chronic obstructive pulmonary disease who participated in a structured aerobic exercise group for 10 weeks showed improvements in cognitive function as compared to patients who did not (Emery, Schein, Hauck, & MacIntyre, 1998).

Next, various hormones have been associated with cognitive function. For instance, low levels of estrogen or testosterone have been related to poorer cognitive function, as have both high or low levels of several thyroid and pituitary hormones, high resting levels of cortisol (a stress hormone), and greater cortisol responses to stress. On the other hand, hormone replacement therapy has been associated with better cognitive function. Examining data from the Baltimore Longitudinal Study on Aging, Dr. Susan M. Resnick and her colleagues at the National Institute on Aging found that postmenopausal women receiving hormone therapy had better memory function than women who did not (Resnick & Maki, 2001).

Genetic factors can also affect cognitive performance. One such factor that has received much attention is the apolipoprotein E (APOE) gene. Although most commonly examined in relation to brain diseases that cause dementia (such as Alzheimer's disease), the presence of a certain variant of the APOE gene known as the E4 allele has also been associated with poorer

cognitive function in healthy people. In addition, Dr. Mary N. Haan and her colleagues at the University of Michigan found that having an APOE E4 allele was related to a greater rate of cognitive decline in people with vascular diseases or diabetes (Haan, Shemanski, Jagust, Manolio, & Kuller, 1999).

Environmental or occupational exposure to chemicals, such as solvents and lead, is toxic to the brain and has been associated with cognitive dysfunction. Both chronic low-level exposure and peak exposures, or a combination thereof, can be problematic. In that regard, Dr. Lisa A. Morrow and her colleagues at the University of Pittsburgh found that a group of journey-person painters with chronic solvent exposure performed most poorly on memory tests after having a recent acute exposure (Morrow, Steinhauer, Condray, & Hodgson, 1997).

Numerous medical diseases have been associated with poorer cognitive function (see Tarter, Butters, & Beers, 2001). Examples include cardiovascular diseases such as hypertension and myocardial infarction (MI) (heart attack), pulmonary diseases such as chronic obstructive pulmonary disease and asthma, pancreatic diseases such as diabetes mellitus, hepatic diseases such as cirrhosis, autoimmune diseases such as systemic lupus erythematosus, various cancers, sleep disorders such as obstructive sleep apnea syndrome, and HIV and AIDS.

Cardiovascular disease presents a good example to discuss further. A negative impact of cardiovascular disease on the brain is indeed not surprising when one considers that the primary purpose of normal cardiovascular function is to supply blood that transports oxygen, glucose, and other essential nutrients to the cells of the body. Because the brain is relatively unable to store nutrients, it is highly dependent upon the cardiovascular system for a constant supply of blood and is quite vulnerable to interruptions of blood flow. Indeed, even a very brief cessation of blood supply to the brain can cause serious damage. Subtle reductions in cerebral blood flow that have been shown to occur in people with cardiovascular disease can therefore have negative short- and long-term consequences for the brain. Many research groups in the United States and Europe have found that a spectrum of cardiovascular diseases, including hypertension (high blood pressure), cardiac arrhythmias, coronary artery disease, MI (heart attack), and even peripheral vascular disease, are associated with poorer cognitive function (see Waldstein & Elias,

2001). Our research group at the University of Maryland, Baltimore County, University of Maryland School of Medicine, and Baltimore Veterans Affairs Medical Center has also found that increasingly severe manifestations of cardiovascular disease have incrementally greater negative impact on cognitive function (Waldstein et al., *in press*).

Many medical and surgical treatments for disease have been shown to affect cognitive performance. However, whereas some studies show improvements in cognitive function when a disease is treated, others show further decrements, and still others show no effect at all. This issue is complicated, because although medications and surgery can often help to manage a chronic medical disease, the underlying disease typically remains present. In addition, many medications can affect the brain by direct and indirect means, as can various surgeries. Examples of medical interventions that have been shown to have some positive effects on cognitive function include oxygen-related treatments for chronic obstructive pulmonary disease and obstructive sleep apnea syndrome, and hemodialysis for renal (kidney) failure. In contrast, certain surgical interventions such as coronary artery bypass surgery can negatively impact cognitive function in a subgroup of patients. Other treatments, such as antihypertensive (blood pressure) medications, have shown both positive and negative effects (albeit small) on cognitive function, sometimes even within the same individuals. For example, in studying the effects of six different antihypertensive agents on cognition, Dr. Matthew F. Muldoon and his colleagues at the University of Pittsburgh found that certain cognitive functions improved, whereas others declined, when people were taking blood pressure medication (Muldoon et al., 2002).

## SUMMARY

There are many aspects of health and disease that affect the brain and therefore our cognitive abilities. These influences can occur in people of all ages. Whereas good health habits are associated with better cognitive function, poor health habits are related to worse cognitive function. Various hormones, genetic factors, chronic medical diseases, and exposure to environmental toxins have also been shown to negatively impact cognitive function. Finally, whereas certain medical and surgical treatments have been shown to be beneficial to cognition, others may create

additional problems. Leading a healthy lifestyle and preventing and treating medical disease are critically important ways to try to preserve cognitive function across the life span.

## COMMUNITY-BASED PARTICIPATORY RESEARCH

Community-based participatory research in public health is a partnership approach to research that equitably involves, for example, community members, organizational representatives, and researchers in all aspects of the research process. All partners contribute their expertise and share responsibility and ownership to enhance understanding of a given phenomenon and to integrate the knowledge gained with interventions to improve the health and well-being of community members (Israel, Schultz, Parker, & Becker, 1998).

There are a number of partnership approaches to research and action that span the social science literature, including participatory research, participatory action research, action research, cooperative inquiry, and empowerment evaluation (Israel et al., 1998). While these approaches differ on several dimensions, each includes the active involvement of all participants in the research process and a commitment to conducting research that will benefit those involved, through the use of research findings to guide policy change and/or through direct interventions. The use of the term *community-based participatory research* makes clear the emphasis on both conducting research within a community context and the critical role of participation and influence of community members in all aspects of the research process.

## KEY PRINCIPLES OF COMMUNITY-BASED PARTICIPATORY RESEARCH

There are a number of key principles or characteristics that guide the development and maintenance of a community-based participatory research (CBPR) partnership. While no one set of principles is applicable to all contexts and participants, there are core underlying perspectives that instruct CBPR efforts. The principles presented here are based on a synthesis of the present knowledge in the field. Although presented here as distinct items, CBPR processes serve to integrate these characteristics.

Drawing upon the literature on group process (Johnson & Johnson, 2003), these principles are relevant to any group that brings together people or organizations with different missions and goals, where there is a need to ensure equitable participation and influence in order to achieve ongoing engagement.

Furthermore, there is a particular emphasis within CBPR efforts to apply these principles in communities where long-standing economic and other inequalities contribute to differences in health status, in opportunities to participate in research, as well as mistrust of researchers and health professionals. Thus, these principles are applicable for research efforts aimed at improving health in all communities, as well as more specifically to those efforts aimed at reducing health disparities. (The principles described below are drawn from Israel et al., 1998, and Israel et al., 2002.)

1. *Acknowledges community as a unit of identity.* Community, as a unit of identity, involves a sense of emotional connection and identification with others, shared norms and values, common symbol systems, similar goals and interests, and desire to meet shared needs. Communities of identity may be either a defined geographic area (e.g., neighborhood) or a geographically dispersed group with a common sense of identity (e.g., ethnic group, gay men and lesbians). A city or other geographic area may include a number of different communities of identity or may be an aggregate of individuals who do not share a sense of identity. CBPR partnerships seek to work with existing communities of identity and also to enhance a sense of community through collaborative processes. Communities of identity may benefit from involving individuals and groups from outside the community who bring additional skills and resources that contribute to their goals.

2. *Begins with and builds on strengths and resources within the community.* CBPR acknowledges and builds on the strengths and resources that exist within communities of identity, for example, skills and assets of individuals, caring and helping networks of social relationships, and mediating structures such as faith-based and community-based organizations. CBPR strives to identify, support, and enhance these strengths and resources that enable community members to work together to improve health and quality of life.

3. *Promotes collaborative, equitable partnership in all aspects of the research, involving an empowering and power-sharing process.* CBPR emphasizes the development and maintenance of collaborative, equitable partnerships, in which all partners share influence and control over all aspects of the research process, starting with the identification by community

members of the issues and concerns to be addressed. Researchers involved in CBPR recognize the inequalities that often exist between themselves and community members. Efforts to create equitable partnerships in the face of these inequalities include the creation of structures and processes that facilitate sharing information, decision-making power, and resources among members of the partnership, with explicit attention to incorporating the expertise of community members.

4. *Facilitates colearning and capacity building among all partners involved.* CBPR promotes colearning and the reciprocal exchange of knowledge, skills, and capacity among all partners, with the goal of enhancing the effectiveness of the CBPR effort, as well as strengthening other endeavors in which partners are involved. For example, researchers learn from the local knowledge that community members have about their community's history, culture, politics, and broader social context, as well as from their administrative and management skills. Similarly, community members may further develop skills in areas such as conducting research and evaluation and grant proposal preparation, and smaller community-based organizations may enhance their capacity to serve as fiduciary for partnership grants.

5. *Combines and creates a balance between research and action for the mutual benefit of all partners.* CBPR aims to contribute to knowledge related to the determinants of health and well-being while combining and balancing that generation of knowledge with change efforts that benefit the communities involved. CBPR partnerships may agree that all research efforts not involve an intervention component, but they commit to the translation of research findings to intervention and policy strategies that will address the concerns of the community.

6. *Focuses on local relevance of public health problems and ecological approaches that address the multiple determinants of health and disease.* CBPR examines public health problems that are of local relevance to the community involved, acknowledging the concept of health from a positive perspective that considers physical, mental, and social well-being. CBPR also focuses on an ecological approach to health that involves individuals, the immediate context in which they live (e.g., family, social network), and the broader context in which they are embedded (e.g., community, society). Accordingly, this ecological

approach attends to multiple determinants of health and disease, including biomedical, social, economic, cultural, and physical environmental factors. CBPR efforts aim to address this complex set of determinants through the integration of multiple units of practice.

7. *Facilitates system development through a cyclical and iterative process.* CBPR facilitates the development of systems (e.g., a partnership) to engage in a cyclical, iterative problem-solving process. The steps in this process may include partnership development and maintenance, community assessment, problem definition, research design, methods development, data collection and analysis, interpretation of data, dissemination of findings, development and implementation of intervention strategies and policy implications, evaluation and specification of learnings, and creation of mechanisms for sustainability.

8. *Disseminates results to all partners and involves them in the dissemination process.* CBPR involves the dissemination of research findings to all partners involved, using language that is understandable and respectful. Feedback of data occurs on an ongoing basis, and results are used to guide interventions and policy changes. The dissemination of findings extends beyond the partnership itself and involves all partners as reviewers and coauthors of publications and as copresenters at conferences.

9. *Promotes a long-term process and commitment.* CBPR involves a long-term process and commitment on the part of all partners to follow the principles described above. CBPR emphasizes the establishment of relationships and commitments that extend beyond a single research project or funding period.

## RATIONALE FOR COMMUNITY-BASED PARTICIPATORY RESEARCH

As summarized by Barbara Israel and colleagues (1998), there are numerous advantages to CBPR that are discussed in the literature. Some of the key rationales for CBPR include that it improves the relevance and usefulness of the research findings; enhances the quality and validity of the research; brings together partners with diverse knowledge, skills and expertise to address complex issues; increases the likelihood of overcoming the understandable distrust of research by communities that have historically been excluded from and been the “subjects” of the research process; applies the knowledge gained to direct resources and

influence policies aimed at benefiting the community; builds bridges across cultural differences that may exist between the partners; strengthens the capacity of all partners to understand and address community concerns; provides additional resources and employment opportunities for marginalized communities; links communities that have been marginalized (based on, e.g., race, class, and gender) with researchers in investigating the effects of marginalization and in actions aimed at its elimination; and improves the health and well-being of the communities involved.

## CBPR EXAMPLE: THE DETROIT COMMUNITY-ACADEMIC URBAN RESEARCH CENTER

### Overview and Mission

There are numerous examples of community-based participatory research efforts that have addressed topics such as diabetes prevention and control, domestic violence, social determinants of health, cancer prevention, the physical environment and childhood asthma, access to quality health care, HIV/AIDS prevention, and environmental justice (for reviews of this literature see Israel et al. 1998; Green et al., 1995; Minkler & Wallerstein, 2002). Here we briefly discuss the Detroit Community-Academic Urban Research Center (URC) as an example of a CBPR partnership that involves representatives from community-based organizations, public health and health care agencies, and academia. The partner organizations are Butzel Family Center, Community Health and Social Services Center, Detroit Health Department, Detroit Hispanic Development Corporation, Friends of Parkside, Henry Ford Health System, Kettering Butzel Health Initiative, Latino Family Services, Southwest Counseling and Development Services, the University of Michigan Schools of Public Health and Nursing, Warren/Conner Development Coalition, and the Centers for Disease Control and Prevention (CDC). The URC began in 1995 and receives core funding from the CDC through its Urban Health Initiative.

The overall mission of the URC is to establish an effective community-based participatory research partnership to jointly identify factors affecting the health and well-being of residents on the east and southwest sides of Detroit and to implement and evaluate interventions and policies to address these factors in ways that recognize, build upon, and enhance the resources and strengths in the communities involved,

toward the end of reducing health disparities. The URC works in two geographic communities of identity: east-side Detroit, which is predominantly African American, and southwest Detroit, which is the area of the city in which the largest percentage of Latinos reside.

### Accomplishments and Benefits

An extensive evaluation of the partnership process has identified accomplishments and benefits of the URC (Israel et al., 2001; Lantz, Viruell-Fuentes, Israel, Softley, & Guzman, 2001). These include the adoption and implementation of operating procedures and CBPR principles; the development of trusting relationships among the partners involved; the implementation of 14 funded CBPR projects, addressing issues such as social determinants of health, diabetes prevention and management, the environment and childhood asthma, and access to quality health care (over \$27 million received); increased collaboration between the African American and Latino communities involved; the hiring of over 150 community members for full-time or part-time positions; the dissemination of results through numerous coauthored publications and presentations; the increased involvement of faculty and students in CBPR projects; and the increased involvement of community partners as guest lecturers in classes and as field preceptors for courses and internships.

### Challenges and Barriers

The URC evaluation has identified a number of challenges and barriers to conducting CBPR (Israel et al., 2001; Lantz et al., 2001). These include establishing and maintaining trust and working relationships among partners; identifying and agreeing upon priorities; managing the significant amount of time required to develop positive relationships and jointly carry out tasks; developing and implementing mutually agreed upon operating procedures (e.g., deciding who participates on the board, how they are selected, how meetings are conducted, how decisions are reached, such as consensus or majority vote); seeking a balance between time spent on process issues related to board development and completing specific tasks, as well as time spent on research as compared to intervention activities; working together across ethnic, cultural, social class, and organizational differences; following agreed upon CBPR principles in practice;

addressing questions raised concerning the scientific quality of the research; proving partnership and intervention success; convincing funders that CBPR may take more time to produce results than non-CBPR approaches; and competing institutional demands (e.g., publishing, grant writing, providing health and social services, community development) that limit the ability of partners to devote the requisite time for URC board and affiliated projects' activities.

### Lessons Learned and Recommendations for Conducting CBPR

A review of the literature on CBPR, including the experiences of the URC, suggests a number of lessons learned and recommendations for conducting CBPR. One of the strengths of a CBPR approach is that it is tailored to the local culture, history, resources, and needs of the communities involved, and thus, flexibility in adapting these lessons learned to new contexts is important. The following are key recommendations (see Israel et al., 1998, 2001, and 2002 for a more in-depth discussion):

- Jointly develop a set of CBPR principles and norms for how members of the partnership are going to work together.
- Establish a balance between the time spent on process issues and the tasks and activities that the partnership wants to conduct.
- Mutually identify and agree upon priority issues, goals, and objectives.
- Emphasize community strengths as well as problems.
- Define *community* and who represents the community (e.g., start small, involving a few highly regarded community-based organizations within communities of identity, gain support and involve top leadership from partner organizations, build on prior history of good working relationships).
- Establish dissemination procedures.
- Apply methodological flexibility and appropriate criteria for judging effectiveness.
- Create and maintain infrastructure.
- Achieve a balance in the distribution of benefits and resources.
- Build upon the cultural diversity of the partners involved.
- Conduct ongoing evaluation of the partnership process.

## CONCLUDING COMMENTS

Addressing disparities in health status between marginalized communities and those with greater access to social and economic resources requires the development of more equitable approaches to research and intervention that are beneficial to the communities involved. CBPR is one approach that involves diverse partners in strategies aimed at increasing knowledge and action to address community-identified needs. While there is no one approach to CBPR, those interested in conducting CBPR can draw upon the principles and lessons learned by others as they develop their own strategies for inquiry and change aimed at improving health and quality of life and reducing health disparities.

## COMMUNITY COALITIONS

Solving complex health issues requires addressing multiple risk factors using a variety of interventions aimed at changing individual, organizational, and community factors. In order to accomplish this, it is necessary to engage various agencies and community leaders and members in processes that allow them to work together effectively. Recognizing this, public health professionals have attempted to capitalize on naturally occurring coalitions that bring together the strengths, capacities, and social structures of communities and various agencies, or have attempted to create new coalitions among these groups. *A coalition is a group that comes together for a common purpose*. A coalition may act together to address the interests of all parties or collaborate to minimize duplication. While there are many different types of groups that individuals and organizations may be part of, and different people have different definitions and names for these groupings, for purposes of this entry a coalition has a diverse membership whose charge is to some extent self-defined or at least modified over time. A coalition may in certain instances be synonymous with what some have called partnerships. However, some partnerships may involve only two organizations with a defined task or set of activities and thus may differ from our current use of the term *coalition*. Similarly, individuals may form a group to accomplish a specific task. Such "task forces" or "teams" differ from our use of the term *coalition* in that they usually have a very clearly defined charge from the outset, are often dominated by professionals, and are not as diverse and fluid as a coalition.

Previous literature has identified several stages of coalition development, each with different tasks that

need to be accomplished in order to be effective. These stages include (a) preformation and formation, (b) action planning and implementation, (c) evaluation, and (d) institutionalization/sustainability.

#### PREFORMATION, FORMATION, AND MEMBERSHIP

Before considering the development of a coalition for creating changes in health and behavior, it is essential to understand the history of community relations, previous experiences with health projects, inter-group relations, and interorganizational relationships (particularly the levels of trust and respect among these individuals and groups), as well as community resources and values. It is also important to understand that other aspects of the social and economic context (e.g., experiences with discrimination and racism, and levels of poverty and unemployment) may influence motivation for and ease of working together. In practice, many coalitions form in response to an experienced need or event, and thus these issues may not be explicitly addressed at the time of formation. Even so, these issues will influence the ability of the coalition to move forward through the other stages and will need to be considered at some point.

The coalition may be composed of professionals from organizations (community organizations, health care centers, social service agencies), a group of grassroots community members, or some combination of these. The coalition may be initiated by funding agencies, professional organizations, or by a group of community members.

It is critical to make decisions regarding membership at the beginning of coalition activities. A coalition with individuals who are all focused on a single issue may limit input and creativity. Alternately, if the effort is categorical and a coalition of organizations and individuals with broad interests is developed, individuals may feel frustrated at being limited in the types of programs and policies that can be developed. In both cases, community support will be lessened rather than enhanced, and this will carry over to, and influence, future endeavors. Another consideration in considering membership of the coalition is agency versus community member involvement. A coalition of service organizations provides grounding in the community and is essential for community-based work. This is, however, different from a coalition in which community agencies/organizations, health

providers, and intended program recipients jointly define the issues to be addressed and plan, implement, and evaluate the programs and/or policies created to address these issues. Another consideration in developing coalition membership is the extent to which it is seen as beneficial to bring together a diverse group in terms of race, class, and ability. Such a diverse group can offer a range of expertise to enhance program effectiveness. Alternately, a diverse group may be able to increase the number of community members who take part in programs or offer support for the coalition agenda. The capacity to realize the benefit of such diversity depends on the level of commitment to ensure that all members have equal opportunities to engage in decision-making processes both within and outside the coalition and to influence the outcomes of the coalition activities. In order to do this, the organizational structure must be jointly defined and established by all coalition members.

In terms of purpose, some coalitions may be focused on categorical issues, such as breast cancer, development of a playground, or improving housing. Other coalitions may form to address broader public health issues such as improved overall access to health care services. Alternately, the process of developing, building, and maintaining relationships among coalition partners may be considered the primary purpose of the coalition.

Regardless of the narrow or broad focus, a coalition needs to decide the level of integration it wants to have with the other agencies and with community members. This can be thought of as a continuum of integration. On one end of the continuum is the desire of agencies and individuals to work together to identify gaps in services, avoid duplication of services, and exchange information to allow for appropriate client referral. The next level of integration involves agencies maintaining their autonomy, agendas, and resources, but beginning to share these resources to work on an issue that is identified as common to all agencies. The next level of integration involves each of the agencies lessening their level of autonomy and beginning to develop joint agendas, joint goals, and joint resources. The coalition may decide to implement joint programs or encourage other groups to implement programs that they collectively deem important and are willing to commit resources to ensure their development and implementation.

The level of integration that is appropriate depends on the desires of the agencies, the length of time that

the coalitions have worked together, and the nature of the problem (short-term “fixable” vs. long-term years to achieve change). Some coalitions may decide to start at a low level of integration and move to higher levels of integration over time; others may start with attempts to engage in projects that require full integration. What is most crucial is that all agencies and community members agree on the level of integration and jointly define their common goals as well as objectives to reach these goals.

In order to make decisions regarding the purpose of the coalition and the level of integration, it is necessary to develop processes for interaction. The ability to do this collaboratively is a function of the coalition’s structure and organization. This includes defining roles and responsibilities of different coalition members, the organization in terms of, for example, the existence and role of subcommittees, and formal and informal methods of communication. In addition, it is essential that coalitions act to define and build their group process skills. These skills include decision making, methods and types of participation among different coalition members, cultural competence, group facilitation, minute taking, agenda development, and conflict management. It is also important that the group structure incorporates methods of recognizing the contributions of both leaders and members. When considering the structural and organizational options, it is important to remember that individuals from different agencies and different community members each have different ways of engaging in these processes. Therefore, any choices regarding policies and procedures must consider the range of possibilities and include training opportunities so that all members of the coalition have the skills necessary to participate in whatever processes are chosen. Given that coalition membership often changes over time, it is critical that these training opportunities and orientation to the decisions made be provided to new members as they join the coalition.

## ACTION PLANNING AND IMPLEMENTATION

Regardless of the level of integration a coalition desires, some degree of skill in the area of action planning and implementation is essential. For some coalitions, the action steps may be to develop referral mechanisms (e.g., forms, shared telephone lists), while other coalitions may decide to implement specific programs or advocate for policy changes. In all

instances, there is some commonality of the skills required. For example, important planning skills include the ability to review existing data to determine priority issues and/or risk factors that contribute to the defined priorities, and to clearly define objectives and develop a work plan (see, e.g., Johnson et al., 1996, and the Community Tool Box, 2003, for additional tips for engaging in these steps).

Many coalitions have members who have these abilities and skills, while other coalitions may request outside technical assistance to engage in these processes. It is essential that these outside resources (consultants, practitioners, and/or academicians) understand and respect the coalition processes and structures and act accordingly. Participatory approaches that recognize the strengths and capacities of all partners (e.g., community-based participatory research) are important to consider when outside technical assistance is requested. In defining and implementing action plans, it is also important that the coalition have access to key decision makers, be able to create and leverage public pressure in support of their initiative, and have access to resources.

## EVALUATION

The evaluation of coalition activities should be consistent with the stage of coalition development. For example, initial evaluation activities should focus on issues such as structure, organization, the coalition’s ability to garner support, and participation of appropriate members. Later evaluation activities can focus on the ability of the coalition to achieve its stated goals and objectives as well as unintended outcomes (that may be positive or negative). In all cases, the methods used (qualitative or quantitative) should be based on the questions asked and the coalition’s ability to utilize the information. While it is important to evaluate coalition processes and outcomes, evaluation activities may be more or less formal and structured, depending on the resources available.

Previous research suggests that not all coalition efforts are successful or effective, and that at times the impact of successful coalitions may have gone undetected because of inappropriate (or weak) evaluation plans. Some common evaluation weaknesses include (a) an evaluation time frame that is too short, (b) an evaluation strategy that focuses on unrealistic, distant health outcomes instead of intermediate endpoints influenced by coalition activity, (c) measures that are

incapable of detecting valid indicators of change, and (d) alternative explanations for effects are not taken into account. For many coalition or partnership endeavors, a realistic scaling back of expectations will offer more opportunities for accountability.

#### INSTITUTIONALIZATION AND SUSTAINABILITY: THE NEED FOR A CRITICAL LENS

To sustain coalition activities, it is often important to assess existing needs and resources. In terms of resources, some coalitions operate with minimal costs expended by the coalition itself in terms of staff and facilities (often with other organizations donating some of these resources). These contributions may or may not continue as the coalition evolves. In addition, there are often personal costs associated with coalition involvement, including exacerbation of conflicts among members and/or other groups. In these instances, it is important to critically reflect on the specific coalition structure and organization and decide if it can achieve the stated goals and objectives. It is also important to assess the extent to which the coalition members and/or community as a whole has developed competing priorities and/or other needs for what are usually limited resources. These emerging community needs may in some instances require dissolving the existing coalition and supporting other coalitions, changing membership of existing coalitions, developing new coalitions, or supporting other approaches and endeavors.

## COMORBID MENTAL AND OTHER PHYSICAL DISORDERS

---

A range of studies has shown that many individuals suffer from mental and other physical disorders at the same time. The suffering experienced by individuals as a result, and the cost in lost productivity and health expenditures, is magnified well beyond the suffering and costs associated with either mental or other physical disorders alone.

Comorbid disorders occur across the life span, from early childhood through the oldest segments of our population, including those with terminal physical disorders. Yet the scope and nature of comorbid mental and other physical disorders remain largely unknown. Limited reliable and valid national or statewide epidemiological data on the incidence and prevalence of these comorbid disorders exist. Little is known about the mechanisms that link comorbid mental and other physical disorders, particularly mechanisms that have a relatively large influence on the development of these comorbid disorders and can also be modified through intervention. Thus, our ability to intervene to prevent or treat adverse comorbid mental and other physical outcomes is limited. While an extensive scientific literature shows that available medications and psychotherapy, especially in combination, effectively treat depression, few studies have specifically examined the optimal treatment approaches for the range of comorbid mental and other physical disorders.

Depression and anxiety are associated with major risk factors for a wide range of comorbid medical disorders, including several leading causes of death among Americans such as heart disease, cancer, strokes, and diabetes (Neugebauer, 1999). These risk factors include smoking, a harmful diet, and lack of regular exercise. By their nature, depression and anxiety, as well as the stigma associated with the disorders and interventions for them, can impede motivation, skills acquisition, and behavior change in all these areas.

The detrimental impact of mental disorders, independent of comorbidity with other physical disorders, in the United States and throughout the world is enormous. For example, according to World Health Organization estimates, unipolar major depression will become the second leading cause of disability worldwide by the year 2020, second only to heart disease (Murray & Lopez, 1996). Among women worldwide, depression will be the leading cause of disability. Other mental disorders, such as bipolar disorder, schizophrenia, and obsessive-compulsive disorders, are also major contributors to disability worldwide. In the United States, mental disorders such as depression and anxiety are prevalent and debilitating (Regier et al., 1993). Five percent to 12% of men and 10% to 25% of women have a major depressive episode during their lifetime, and many more have depressive disorders that fall short of criteria for major depressive disorder (Kessler et al., 1994).

Comorbid depression and heart disease are briefly discussed as examples because these two disorders are among the most common facing Americans and because this type of comorbidity has received far more research attention than any other. Heart disease is by far the leading cause of death in the United States among both men and women. If current trends continue, about one in three Americans will die of some form of heart disease. One out of every two American men and one out of every three women age 40 and younger develop heart disease at some time in their lives (Levy, 1999).

As yet, poorly understood mechanisms link depression and heart disease, although hypotheses include increased platelet aggregation and proinflammatory cytokines, and decreased heart rate variability (see Schulz, Martire, Beach, & Scheier, 2000, for a detailed discussion of potential mechanisms). Among men followed for 40 years, those who reported clinical depression were more than twice as likely to develop coronary artery disease than those who did not report clinical depression. The increased risk associated with clinical depression was present even for myocardial infarctions occurring 10 years after the onset of the first depressive episode (Ford et al., 1998).

Penninx et al. (2001) examined the risk for cardiac mortality in community-dwelling individuals over age 55 with and without cardiac disease at baseline. Individuals with depression were three to four times more likely to die over the next 4 years than those

without depression. Furthermore, those with diagnosable depression were about twice as likely to die as those with depressive symptoms.

A history of depression increases the risk of further depression during hospitalizations for heart disease and after discharge. Depression in hospital is associated with an increased risk of mortality 18 months after discharge (Frasure-Smith, Lesperance, & Talajic, 1995). Depression also appears to increase the risk for strokes. Simonsick, Wallace, Blazer, and Berkman (1995), in *Depressive Symptomatology and Hypertension-Associated Morbidity and Mortality in Older Adults*, found that among those age 65 and older, rates of stroke were 2.3 to 2.7 times higher in persons with "high" versus "low" levels of depressive symptoms. Mild depressive symptoms in those older than 65 are associated with an increased likelihood of becoming disabled and a decreased chance of recovery, regardless of age, sex, and other factors that contribute to physical disability (Cronin-Stubbs et al., 2000).

Thus, interventions aimed at comorbid disorders, such as depression and heart disease, would have enormous public health significance because of the widespread suffering caused by mental disorders themselves. For example, the average length of disability and the disability relapse rate associated with depression were equal to or greater than those associated with common, chronic medical problems such as diabetes, hypertension, recent myocardial infarction, and congestive heart failure (Hays, Wells, Sherbourne, Rogers, & Spritzer, 1995). While available medications and psychotherapy, especially in combination, effectively treat depression, more research is needed to find the optimal approaches for treating depression when it is comorbid with other specific physical disorders.

With respect to current treatment for mental disorders such as depression, depressed persons from the community are more likely to visit a primary care physician than a mental health professional, and most prescriptions for antidepressants are dispensed in general medical care (Ford, 2000; Regier et al., 1993). Between 30% and 40% of primary care patients screen positive for significant levels of emotional distress, and as many as 25% meet criteria for a mental disorder diagnosis (Roter et al., 1997). In one study, almost one third of individuals older than 60 visiting a primary care physician had at least one active mental disorder diagnosis (Lyness, Caine, King, Cox, & Yoediono, 1999). But half of mental disorders meeting

diagnostic criteria are not recognized by primary care physicians (Schulberg et al., 1996). Basic research, however, might facilitate physicians' ability to recognize and treat or refer individuals with depression.

Thus, much research is needed to improve our knowledge base and our ability to effectively intervene. This research should include (a) epidemiological studies that elucidate the frequency and distribution patterns of comorbid mental and other physical disorders across gender and racial/ethnic minority groups and the life span, (b) studies of biological, behavioral, and psychosocial risk and protective processes underlying comorbid mental and other physical disorders to clarify which processes have the greatest relative influence on the development of these disorders and can potentially be modified through intervention, (c) tests of innovative pharmacological, behavioral, psychosocial, or environmental interventions for comorbid disorders in actual practice settings, and (d) research on the impact of separate organizational systems and different financing mechanisms for comorbid mental and other physical disorders.

—Peter Muehrer

## COMPLEMENTARY AND ALTERNATIVE MEDICINE

---

A variety of terms (*complementary, alternative, unconventional, unproven, and unorthodox medicine*)

refer to approaches not part of standard medical practice in the Western world (Eisenberg et al., 1993). The term *complementary and alternative medicine* (CAM) is used most commonly to refer to these practices, but has not been well defined. CAM covers a broad range of healing philosophies, approaches, and therapies that mainstream Western (conventional) medicine does not commonly use, accept, study, or make available (National Center for Complementary and Alternative Medicine [NCCAM], 2002a). Some offer systems of assessment and treatment (e.g., homeopathy, traditional Chinese medicine, ayurveda); others complement conventional treatment with various supportive practices, products, or techniques (e.g., herbal remedies, meditation training).

The National Institutes of Health Panel on Definition and Description of CAM in 1995 defined CAM as “a broad domain of healing resources that encompasses all health systems, modalities and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period” (p. 50). However, this and many other definitions fail to identify what CAM actually is, which is a prerequisite for development of a valid body of knowledge about CAM use and its determinants. To address this, categories of CAM have been distinguished. For example, NCCAM (2002b) has identified five major CAM domains: alternative medical systems, mind-body interventions, biologically based treatments, manipulative and body-based methods, and energy therapies.

Another problematic issue related to labeling and defining CAM is the use of the term *medicine*. Instead of *medicine*, the term *health care* has been proposed (Crellin, Andersen, & Connor, 1997; Health Canada, 2001). Health care consists of all services, products, and activities used by individuals for the purpose of promoting, maintaining, monitoring, or restoring health (Last, 1983). Many CAM users and practitioners are focused on prevention more than treatment.

A thorny challenge has been the distinction (or lack thereof) between “complementary and alternative medicine” and behavioral medicine. Within the National Institutes of Health, offices for both areas were established to encourage cross-institute initiatives; however, the broad and vague definition of CAM led to considerable overlap between the two. Such trends as increased coverage of CAM within managed care without differentiating practices with a

solid foundation in behavioral research exacerbated the problem. While there now is considerable rapprochement (e.g., the creation within the Society of Medicine of a special interest group: Complementary, Alternative, and Integrative Medicine), fundamental conceptual issues remain.

## CONCEPTUAL DIFFERENCES BETWEEN CAM AND CONVENTIONAL MEDICINE

Many types of CAM, in particular complementary health systems, have a common underlying philosophy that includes a focus on health and improving well-being, rather than on disease (Micozzi, 1996). CAM systems are based on a holistic paradigm, which views diseases as having multiple causes amenable to multiple therapeutic interventions through a variety of biochemical, environmental, psychological, social, spiritual, and energetic forces. Therefore, making a diagnosis does not focus on objective signs and symptoms but on evaluating the nature of physical, emotional, structural, or energetic imbalance. Treatment focuses on attempts to strengthen constructive forces and restore balance, based on the fundamental belief in the self-healing capacity of the body. While biomedicine tends to assume that all individuals are basically the same and treats individuals with similar diagnoses the same, CAM is more likely to assume that all individuals are different and, therefore, treatment consists of individualized constellations of therapeutic activities. These features lead to the encouragement of active participation in disease management rather than passive acceptance of prescribed treatment. It should be clear that these differences may be overstated and a matter of degree rather than a clear dichotomy. For example, the patient-centered approach to patient care, increasingly promoted in family medicine (Stewart et al., 1995), emphasizes a holistic philosophy.

## CAM USE

Throughout history, people have used approaches that replace or complement conventional health care. However, it was not until the early 1990s that the extent of this behavior became clear. Eisenberg et al. (1993) were the first to examine CAM use by the general population. They found that 34% of Americans had used at least one alternative treatment during the past year (1990) and 11% had seen an alternative

health care provider. One of the most frequently discussed findings of this study is that about 60% of respondents did not inform their medical doctor of their use of CAM. In a follow-up survey in 1997 (Eisenberg et al., 1998), CAM use had increased to 42%. Fifty-eight percent of CAM treatments were used, at least in part, to prevent illness from occurring or to maintain health and vitality. There was no change in disclosure rates.

Utilization rates in other countries have been estimated at 50% in Canada (Ramsay, Walker, & Alexander, 1999), 49% in Australia (MacLennan, Wilson, & Taylor, 1996), 28% in the United Kingdom, and 65% in Germany (Pittler, 2001). These differences in rates may be partly due to differences in the definition of CAM. For example, some surveys differentiate explicitly between CAM practices and substances and CAM practitioners, and others combine them. Due to these differences, it is difficult to compare CAM use between these countries. Relaxation techniques, herbal medicine, massage therapy, and chiropractic were most common in the United States and Canada (Eisenberg et al., 1998; Ramsay et al., 1999). In Australia, vitamins (nonprescribed) and mineral supplements were commonly mentioned (MacLennan et al., 1996). There are many differences within and between countries in Europe; however, the use of homeopathy and acupuncture appears to be common (Pittler, 2001). CAM use also varies with geographic, historical, and political settings and acceptance by the medical community.

These surveys generally show that CAM users are more likely to be female, be better educated, have higher incomes, and to have chronic conditions (from allergic to musculoskeletal as well as terminal or potentially terminal illness). A recent survey (Druss & Rosenheck, 1999) suggested that less than 2% of the population relies solely on alternative care, supporting the use of the term complementary rather than alternative medicine.

### Reasons for CAM Use

Furnham (1994) distinguished between factors “pulling” people toward CAM and factors “pushing” people away from conventional medicine. These factors form hypotheses about reasons for CAM use, which could potentially assist in predicting whether people will use CAM and which CAM approach they will use. Push factors include dissatisfaction with

conventional medicine, such as lack of effectiveness, adverse effects, and poor patient-physician communication. Pull factors include compatibility between the underlying philosophy of certain approaches and patients’ own beliefs (such as holism, emphasis on well-being, and an active patient role), personal control over treatment, patient-practitioner relationship (e.g., on equal terms, time for discussion and attention to emotional, spiritual, and other nonphysical factors), and belief in the effectiveness of CAM.

Astin (1998) tested the relationships between dissatisfaction with conventional care, need for personal control, and philosophical congruence with own beliefs in a random sample of 1,035 American residents. He found that only philosophical congruence was predictive of CAM use. Rather than being pushed toward CAM due to disillusionment, participants were pulled toward CAM because it is seen as more compatible with their values and beliefs about health and illness. Surveys of specific patient populations suggest that for some categories of patients, different reasons apply than for others. In addition, it is misleading to combine all CAM modalities, as reasons for the use of one may be different from reasons to use others.

Current societal trends are influencing the growth in CAM use. These include the increase in prevalence of chronic diseases; increasing access to health information, in particular via the Internet; increased interest in well-being and personal spirituality; declining faith that scientific breakthroughs in conventional medicine will have positive effects on personal health; and an increase in personal responsibility and shared decision making (e.g., Jonas, 2000).

### EVIDENCE-BASED CAM PRACTICE

CAM is criticized for the lack of empirical evidence of effectiveness. Many CAM systems have been around largely unchanged for centuries, and the central principles of these traditions have not been advanced with new observations, hypotheses-driven testing, or peer review. The unprecedented growth of CAM has outstripped our ability to provide the evidence base needed to ensure appropriate efficacy and safety guidelines. In addition, current methods to assess efficacy, such as randomized controlled trials, are not as easy to apply to CAM as to conventional treatments. Clinical investigations are complicated by the fact that many CAM treatments involve complex, individualized treatments and many herbal

preparations/oral supplements that lack standardization. Conventional outcomes measures often are not appropriate, as they do not fit with the CAM philosophy, for example, quality-of-life measures that lack a spiritual component. Patients often have strong beliefs about CAM interventions, which affect recruitment and randomization. Finally, the patient-provider relationship is considered a crucial part of the intervention, rather than a confounding variable (Nahin & Straus, 2001).

Arising from both the lack of research and the lack of regulation is the potential for harms resulting from CAM. CAM is often seen as more natural and, therefore, safe. However, many direct effects such as allergic or toxic reactions or drug interactions have been identified. Indirect harms consist of missed diagnoses or delaying diagnosis or conventional treatment. Harm in this case may be due to insufficient or substandard training of CAM practitioners. Finally, unjustifiable financial or emotional hardships have been identified as indirect harms.

## FUTURE DIRECTIONS

Demand for CAM will continue to expand. The big question for the future is whether CAM will be able to coalesce across therapies and develop its own organizational structure independent of medicine. Or will it eventually be incorporated into the conventional medical system as the evidence base develops? It is too early to say. Different health care systems will find different solutions, and what evolves may be a mixture of several options.

The concept of integrated medicine has been developing rapidly over the past 2 to 4 years, but so far, it is poorly defined. One useful definition is based on the work of Way and Jones (2000): "Integrative practice is an inter-professional process for communication and decision making that enables the separated and shared knowledge and skills of care providers to synergistically influence the client/patient care provided" (p. 3). Health care consumers are relatively advanced in integrating CAM and conventional medicine, and they select practitioners and products from all categories of health care services to create a package that meets their personal needs and beliefs. Consumer demand has spurred some conventional health care providers to make referrals to CAM practitioners, to provide some of these services, and to become educated regarding safety, efficacy, and underlying assumptions of different CAM approaches.

Partly based on consumer and practitioner involvement in integrated care, there is an increasing number of new initiatives in the United States, Canada, and Europe that seek to provide integrated health care using new and innovative models. However, at institutional, professional, regulatory, and health policy and system levels, integration is not (yet) taking place to any major degree. In a thoughtful article, Bausell and Berman (2002) have described the issues around integrative medicine as a "consumer driven continuation of the biomedical versus the biopsychosocial controversy" (p. 28). They suggest that the public itself may be in the process of inextricably changing medicine with or without the discipline's blessing or consent. Whatever the outcome, it is essential that investigators, CAM, and conventional health care providers and policymakers aim for the provision of "both good medicine and good science" (Bausell & Berman, 2002, p. 32).

The final question is how health and behavior researchers will respond to this opportunity. As a community, behavioral and social scientists have much to offer based on the long tradition of effective research to practice in areas such as behavioral medicine and health promotion. To the extent that the CAM community and the health and behavior research community share a common vision of evidence based and integrated practice, they might gain from working together. A useful first step would be to collaborate on issues related to definition, delivery models, and research methods.

## CONFOUNDING

---

The word *confounding* has been used to refer to at least three distinct concepts. In the oldest and most widespread usage, confounding is a source of bias in estimating causal effects. This bias is sometimes informally described as a mixing of effects of extraneous factors (called confounders) with the effect of interest. This usage predominates in nonexperimental research, especially in epidemiology and sociology. In a second and more recent usage originating in statistics, confounding is a synonym for a change in an effect measure upon stratification or adjustment for extraneous factors (a phenomenon called *noncollapsibility* or *Simpson's paradox*). In a third usage, originating in the experimental-design literature, confounding refers to inseparability of main effects and interactions under a particular design. The three concepts are closely related and are not always distinguished from one another. In particular, the concepts of confounding as a bias in effect estimation and as noncollapsibility are often treated as equivalent, even though they are not. Only the former concept will be described here; for more detailed coverage and comparisons of concepts see Greenland and Rothman (1998), Greenland and Pearl (1999), Greenland and Morgenstern (2001), and Pearl (2000).

## CONFOUNDING AS A BIAS IN EFFECT ESTIMATION

A classic discussion of confounding in which explicit reference is made to “confounded effects” is Mill (1843/1956, chap. 10), although in Chapter 3 Mill lays out the primary issues and acknowledges Francis Bacon as a forerunner in dealing with them. There, he lists a requirement for an experiment intended to determine causal relations:

None of the circumstances [of the experiment] that we do know shall have effects susceptible of being *confounded* with those of the agents whose properties we wish to study [emphasis added].

In Mill’s time, the word *experiment* referred to an observation in which some circumstances were under the control of the observer, as it still is used in ordinary English, rather than to the notion of a comparative trial. Nonetheless, Mill’s requirement suggests that a comparison is to be made between the outcome of our “experiment” (which is, essentially, an uncontrolled trial) and what we would expect the outcome to be if the agents we wish to study had been absent. If the outcome is not as one would expect in the absence of the study agents, then Mill’s requirement ensures that the unexpected outcome was not brought about by extraneous “circumstances” (factors). If, however, those circumstances do bring about the unexpected outcome, and that outcome is mistakenly attributed to effects of the study agents, then the mistake is one of confounding (or confusion) of the extraneous effects with the agent effects.

Much of modern literature follows the same informal conceptualization given by Mill. Terminology is now more specific, with *treatment* used to refer to an agent administered by the investigator and *exposure* often used to denote an unmanipulated agent. The chief development beyond Mill is that the expectation for the outcome in the absence of the study exposure is now almost always explicitly derived from observation of a control group that is untreated or unexposed. For example, Clayton and Hills (1993) state of observational studies,

There is always the possibility that an important influence on the outcome . . . differs systematically between the comparison [exposed and unexposed] groups. It is the possible [that] part of the apparent effect of exposure

is due to these differences, [in which case] the comparison of the exposure groups is said to be *confounded* [emphasis in the original].

In fact, confounding is also possible in randomized experiments owing to systematic improprieties in treatment allocation, administration, and compliance. A further and somewhat controversial point is that confounding (as per Mill’s original definition) can also occur in perfect randomized trials due to *random* differences between comparison groups (Fisher, 1935).

## THE POTENTIAL-OUTCOME MODEL

Various models of confounding have been proposed for use in statistical analyses. Perhaps the one closest to Mill’s concept is based on the *potential-outcome* or counterfactual model for causal effects. Suppose we wish to consider how a health-status (outcome) measure of a population would change in response to an intervention (population treatment). More precisely, suppose our objective is to determine the effect that applying a treatment  $x_1$  had or would have on an outcome measure  $\mu$  relative to applying treatment  $x_0$  to a specific target population A. For example, Cohort A could be a cohort of breast-cancer patients, treatment  $x_1$  could be a new hormone therapy,  $x_0$  could be a placebo therapy, and the measure  $\mu$  could be the 5-year survival probability. The treatment  $x_1$  is sometimes called the *index* treatment, and  $x_0$  is sometimes called the *control* or *reference* treatment (which is often a standard or placebo treatment).

The potential-outcome model posits that, in Population A,  $\mu$  will equal  $\mu_{A1}$  if  $x_1$  is applied,  $\mu_{A0}$  if  $x_0$  is applied; the causal effect of  $x_1$  relative to  $x_0$  is defined as the change from  $\mu_{A0}$  to  $\mu_{A1}$ , which might be measured as  $\mu_{A1} - \mu_{A0}$  or  $\mu_{A1}/\mu_{A0}$ . If A is given treatment  $x_1$ , then  $\mu$  will equal  $\mu_{A1}$  and  $\mu_{A1}$  will be observable, but  $\mu_{A0}$  will be unobserved. Suppose, however, we expect  $\mu_{A0}$  to equal  $\mu_{B0}$ , where  $\mu_{B0}$  is the value of the outcome  $\mu$  observed or estimated for a population B that was administered treatment  $x_0$ . The latter population is sometimes called the control or reference population. *Confounding* is said to be present if  $\mu_{A0} \neq \mu_{B0}$ , for then there must be some difference between Populations A and B (other than treatment) that is affecting  $\mu$ .

If confounding is present, a naive (crude) association measure obtained by substituting  $\mu_{B0}$  for  $\mu_{A0}$  in an effect measure will not equal the effect measure, and

the association measure is said to be *confounded*. For example, if  $\mu_{A0} \neq \mu_{B0}$ , then  $\mu_{A1} - \mu_{B0}$ , which measures the association of treatments with outcomes *across* the populations, is confounded for  $\mu_{A1} - \mu_{A0}$ , which measures the effect of treatment  $x_1$  on Population A. Thus, to say an association measure  $\mu_{A1} - \mu_{B0}$  is confounded for an effect measure  $\mu_{A1} - \mu_{A0}$  is to say these two measures are not equal.

The preceding potential-outcome model of confounding gradually emerged through attempts to separate effect measures into a component due to the effect of interest and a component due to extraneous effects (Bross, 1967; Groves & Ogburn, 1928; Kitagawa, 1955; Miettinen, 1972). It is closely related to graphical (causal diagram) and structural-equations models familiar in social sciences (Greenland & Brumback, 2002). One noteworthy aspect of this approach is that confounding depends on the outcome measure. For example, suppose populations A and B have a different 5-year survival probability  $\mu$  under placebo treatment  $x_0$ ; that is, suppose  $\mu_{B0} \neq \mu_{A0}$ , so that  $\mu_{A1} - \mu_{B0}$  is confounded for the actual effect  $\mu_{A1} - \mu_{A0}$  of treatment on 5-year survival. It is then still possible that 10-year survival,  $m$ , under the placebo would be identical in both populations; that is,  $\mu_{A0}$  could still equal  $\mu_{B0}$ , so that  $\mu_{A1} - \mu_{B0}$  is not confounded for the actual effect of treatment on 10-year survival. (We should generally expect no confounding for 200-year survival, since no treatment is likely to raise the 200-year survival probability of human patients above zero.)

A second noteworthy point is that confounding depends on the target population of inference. The preceding example, with A as the target, had different 5-year survivals  $\mu_{A0}$  and  $\mu_{B0}$  for A and B under placebo therapy, and hence  $\mu_{A1} - \mu_{B0}$  was confounded for the effect  $\mu_{A1} - \mu_{A0}$  of treatment on Population A. A lawyer or ethicist may also be interested in what effect the hormone treatment would have had on Population B. Writing  $\mu_{B1}$  for the (unobserved) outcome under treatment, this effect on B may be measured by  $\mu_{B1} - \mu_{B0}$ . Substituting  $\mu_{A1}$  for the unobserved  $\mu_{B1}$  yields  $\mu_{A1} - \mu_{B0}$ . This measure of association is confounded for  $\mu_{B1} - \mu_{B0}$  (the effect of treatment  $x_1$  on 5-year survival in Population B) if and only if  $\mu_{A1} \neq \mu_{B1}$ . Thus, the same measure of association,  $\mu_{A1} - \mu_{B0}$ , may be confounded for the effect of treatment on neither, one, or both of Populations A and B, and may or may not be confounded for the effect of treatment on other targets.

## CONFOUNDERS (CONFOUNDING FACTORS)

A third noteworthy aspect of the potential-outcome model is that it invokes no explicit differences (imbalances) between Populations A and B with respect to circumstances or covariates that might influence  $\mu$  (Greenland & Robins, 1986). Clearly, if  $\mu_{A0}$  and  $\mu_{B0}$  differ, then A and B must differ with respect to factors that influence  $\mu$ . This observation has led some authors to define confounding as the presence of such covariate differences between the compared populations. Nonetheless, confounding is only a consequence of these covariate differences. In fact, A and B may differ profoundly with respect to covariates that influence  $\mu$ , and yet confounding may be absent. In other words, a covariate difference between A and B is a necessary but not sufficient condition for confounding. This is because the impact of covariate differences may balance each other out, leaving no confounding.

Suppose now that Populations A and B differ with respect to certain covariates, and that these differences have led to confounding of an association measure for the effect measure of interest. The responsible covariates are then termed *confounders* of the association measure. In the above example, with  $\mu_{A1} - \mu_{B0}$  confounded for the effect  $\mu_{A1} - \mu_{A0}$ , the factors responsible for the confounding (i.e., the factors that led to  $\mu_{A0} \neq \mu_{B0}$ ) are the confounders. It can be deduced that a variable cannot be a confounder unless it can affect the outcome parameter  $\mu$  within treatment groups and it is distributed differently among the compared populations (e.g., see Yule, 1903, who however uses terms such as “fictitious association” rather than confounding). These two necessary conditions are sometimes offered together as a definition of a confounder.

Nonetheless, counterexamples show that the two conditions are not sufficient for a variable with more than two levels to be a confounder (Greenland et al., 1999).

## PREVENTION OF CONFOUNDING

Perhaps the most obvious way to avoid confounding in estimating  $\mu_{A1} - \mu_{A0}$  is to obtain a reference population B for which  $\mu_{B0}$  equals  $\mu_{A0}$ . Among epidemiologists, such a population is sometimes said to be *comparable* to or *exchangeable* with A with respect to the outcome under the reference treatment. In practice, such a population may be difficult or

impossible to find. Thus, an investigator may attempt to construct such a population, or to construct exchangeable index and reference populations. These constructions may be viewed as design-based methods for the control of confounding.

Perhaps no approach is more effective for preventing confounding by a known factor than *restriction*. For example, gender imbalances cannot confound a study restricted to women. However, there are several drawbacks: restriction on enough factors can reduce the number of available subjects to unacceptably low levels and may greatly reduce the generalizability of results as well. Matching the treatment populations on confounders overcomes these drawbacks and, if successful, can be as effective as restriction. For example, gender imbalances cannot confound a study in which the compared groups have identical proportions of women.

Unfortunately, differential losses to observation may undo the initial covariate balances produced by matching. Neither restriction nor matching prevents (although it may diminish) imbalances on unrestricted, unmatched, or unmeasured covariates. In contrast, *randomization* offers a means of dealing with confounding by covariates not accounted for by the design. It must be emphasized, however, that this solution is only probabilistic and subject to severe constraints in practice.

Randomization is not always feasible or ethical, and many practical problems, such as differential loss and noncompliance, can lead to confounding in comparisons of the groups actually receiving treatments  $x_1$  and  $x_0$ . One somewhat controversial solution to non-compliance problems is *intent-to-treat analysis*, which defines the comparison groups A and B by treatment assigned rather than treatment received. Confounding may, however, affect even intent-to-treat analyses, and (contrary to widespread misperceptions) the bias in those analyses can be away from the null (exaggerating an effect) (Robins, 1998). For example, the assignments may not always be random, as when blinding is insufficient to prevent the treatment providers from protocol violations. And, purely by bad luck, randomization may itself produce allocations with severe covariate imbalances between the groups (and consequent confounding), especially if the study size is small (Fisher, 1935; Rothman, 1977). *Blocked* (matched) randomization can help ensure that random imbalances on the blocking factors will not occur, but it does not guarantee balance of unblocked factors.

## ADJUSTMENT FOR CONFOUNDING

Design-based methods are often infeasible or insufficient to prevent confounding. Thus, there has been an enormous amount of work devoted to analytic adjustments for confounding. With a few exceptions, these methods are based on observed covariate distributions in the compared populations. Such methods can successfully control confounding only to the extent that enough confounders are adequately measured. Then, too, many methods employ parametric models at some stage, and their success may thus depend on the faithfulness of the model to reality. These issues cannot be covered in depth here, but a few basic points are worth noting.

The simplest and most widely trusted methods of adjustment begin with *stratification* on confounders. A covariate cannot be responsible for confounding within internally homogeneous strata of the covariate. For example, gender imbalances cannot confound observations within a stratum composed solely of women. More generally, comparisons within strata cannot be confounded by a covariate that is unassociated with treatment within strata. This is so regardless of whether the covariate was used to define the strata. Thus, one need not stratify on all confounders in order to control confounding. Furthermore, if one has accurate background information on relations among the confounders, one may use this information to identify sets of covariates sufficient for control of confounding (Pearl, 2000).

Some controversy has occurred about adjustment for covariates in randomized trials. Although Fisher asserted that randomized comparisons were “unbiased,” he also pointed out that they could be confounded in the sense used here (see Fisher, 1935, p. 49). Resolution comes from noting that Fisher’s use of the word *unbiased* referred to the design, and was not meant to guide analysis of a given trial. Once the trial is under way and the actual treatment allocation is completed, the unadjusted treatment-effect estimate will be biased if the covariate is associated with treatment, and this bias can be removed by adjustment for the covariate (Rothman, 1977; Greenland & Robins, 1986).

## CONTROL AND HEALTH

---

When individuals are able to determine or influence what is happening to them, or what will happen to them, those individuals are said to be “in control.” Control is a central construct in psychology, and being in control is a universally desired state of existence for most persons. In the health care arena, control has typically been linked to positive health outcomes (Walker, 2001). Control can be either real or illusory

(Taylor & Brown, 1988). In the latter case, it is the perception of control that matters, especially because the amount of real control we can have over our health is limited. Whether or not one can actually influence health behaviors and outcomes, the perception that one has control is often sufficient to reap its benefits.

Most of the work concerning control and health has involved control beliefs rather than actual control. *Beliefs* about control in the context of health refer to the thoughts (or cognitions) an individual has regarding the ability to influence health behavior, health status (or other health outcomes), or health care. Control beliefs are one of a number of hypothesized determinants of health behavior and health outcome (Wallston, 2001a, 2001b).

## TYPES OF CONTROL BELIEFS

### Locus of Control

Rotter (1966) coined the term “locus of control” to refer to an individual’s belief as to whether control of valued reinforcements (i.e., outcomes) is *internal*—that is, due to who the individual is or what the individual does—versus *external*—that is, due to the actions of other people, fate, luck, or chance. Locus of control (LOC) is a generalized expectancy construct within Rotter’s (1954) social learning theory. Generalized expectancies are traitlike in that they guide behavior across many situations in respect to many reinforcers. Rotter (1966) conceived of LOC as being unidimensional, and the I-E Scale he developed to assess this construct was scored accordingly: high scores on the I-E Scale reflected an external belief orientation, while low scorers were called “internals.” Strickland (1978) reviewed the early studies linking the I-E Scale to physical and mental health variables.

Following Rotter’s lead, a unidimensional health locus of control (HLC) instrument was developed and published by Wallston, Wallston, Kaplan, and Maides (1976). In their initial studies, Wallston et al. (1976) demonstrated that the HLC Scale did a better job than Rotter’s I-E Scale in predicting health-related information-seeking and weight loss, especially for individuals who highly valued good health as a reinforcement. Health researchers began to choose the HLC Scale over the I-E Scale when studying health-related phenomena.

By the mid 1970s, however, researchers began to question the unidimensionality of both the I-E and HLC scales. Internality and externality were seen as

orthogonal dimensions rather than opposite ends of a continuum. Levenson (1973) developed the I, P, and C Scales to assess separately internal LOC beliefs from two types of external LOC beliefs: powerful others and chance. Following Levenson's schema, Wallston, Wallston, and DeVellis (1978) published Forms A and B of the Multidimensional Health Locus of Control (MHLC) Scales. These two forms of the MHLC have a similar factor-structure to Levenson's scales and have been widely used by health researchers throughout the world looking for a measure of control over one's health status. Early work with these measures was reported in two chapters (Wallston & Wallston, 1981, 1982). The most consistent findings have been (a) internal HLC is related to carrying out recommended health behaviors, especially by individuals who highly value good health, (b) internal HLC is related to self-reported health status, and (c) chance HLC is related to depressed mood and other indicators of psychological distress.

Form C of the MHLC (Wallston, Stein, & Smith, 1994) is a generic instrument intended for individuals already diagnosed with a medical condition. By changing the word *condition* in each item, Form C is used to assess persons' LOC beliefs over a particular existing health problem (e.g., arthritis, cancer, diabetes). The "powerful others" dimension in Form C is further broken down into two separate dimensions: doctors and other people. In keeping with an increasing interest in religion and health, Wallston and colleagues (Wallston et al., 1999) have developed a God Locus of Health Control subscale as a means of assessing persons' beliefs about God's control of their health. This new subscale can be used independently or in conjunction with any of the other forms of the MHLC.

Regardless of which form of the MHLC is administered, the preponderance of research with these scales has shown that health *locus* of control beliefs, by themselves, only account for a relatively small percentage of the variance in measures of health behavior and/or health status (Wallston, 1992, 2001b). The *place* where control is perceived to reside is less important than whether or not the individual believes that control exists, even if that control is illusory (Wallston, 2001a, 2001b). Other types of control-related beliefs (enumerated below) often explain a greater amount of variance in health-related measures than does LOC. LOC measures, such as the MHLC, may perform better as moderators than as main effect

predictors (Wallston, 1992; Wallston & Smith, 1994). For instance, the interaction of trust of doctors and the belief that doctors are responsible for one's health status may be more predictive of adherence to one's medical regimen than either predictor alone.

### Perceived Competence, Mastery, and Self-Efficacy

Whereas locus of control is only an imperfect indicator of the perception of control, other constructs such as perceived competence, mastery, and self-efficacy are more directly indicative of the belief that one is in control, particularly of one's behavior. Both mastery (Pearlin & Schooler, 1978) and perceived competence (cf. White, 1959) refer to control over situations and outcomes, as well as to behaviors. Self-efficacy, as originally conceived of by Bandura (1977), was highly situation-specific; it stood for the degree of confidence a person had in his or her ability to successfully carry out a specific behavior in a specific situation. Over the years, Bandura and others have endorsed a generalization of the self-efficacy construct so that it now is more similar to a sense of mastery or perceived competence (see Bandura, 1997). Persons are self-efficacious to the degree that they believe they can do whatever is necessary to obtain valued reinforcements in whatever situation they find themselves. Another close construct to self-efficacy is perceived behavioral control, a key predictor of behavior and behavioral intention in Ajzen's Theory of Planned Behavior (Ajzen, 1991).

As with LOC, attempts have been made to develop health-related measures of self-efficacy and perceived competence. An example of the former is the arthritis self-efficacy scales developed by Kate Lorig and her colleagues (Lorig, Chastain, Ung, Shoor, & Holman, 1989). Clinical researchers have used these measures as indicators of mediators of outcomes of a self-management program for persons with arthritis and other chronic medical conditions (Lorig, Mazonson, & Holman, 1993). The Perceived Health Competence Scale (Smith, Wallston, & Smith, 1995) is an example of the latter approach. Persons scoring high on the PHCS have high scores on self-rated health and psychological well-being (Smith et al., 1995).

### Learned Helplessness

Feeling helpless is the opposite of feeling in control. When a person feels helpless, the person believes

there is nothing he or she can do to improve a bad situation (such as being diagnosed with a terminal illness or being told that there are no treatments for a serious medical condition). Like other beliefs, helplessness is learned (Seligman, 1975). Believing oneself to be helpless in the face of adverse health circumstances is associated with motivational, behavioral, and affective deficits (Walker, 2001). As an example of research done with this construct, Stein, Wallston, and Nicassio (1988) showed that believing oneself helpless in the face of rheumatoid arthritis correlates highly with depressive symptomatology, pain, and functional impairment, and also that changes over time in arthritis helplessness predicts change in pain and depressive symptoms.

## ALTERING CONTROL

The vast majority of research relating control and health has been correlational in design, and much of that research has been cross-sectional rather than longitudinal. Typically, one or two measures of perceived health control are correlated with one or more measures of health behavior or health status. When a positive association is found using this type of research design, it is difficult to determine whether there is a causal relationship between control and health, and, if so, what the causal direction really is. It is, perhaps, more logical to conclude that perceptions of control over health are determined by knowledge of one's prior health behavior or health status than vice versa. Only by manipulating the degree of control a person has, or *thinks* one has, and measuring subsequent changes in health behavior or health status can researchers hope to pin down the causal path between control and health.

It is not unreasonable to assert that most forms of health education, disease prevention, and patient education are designed to give patients more control, or a greater sense of control, over their health. Many of these programs assess participants' self-efficacy or other control beliefs as one means of evaluating whether or not the program is effective in meeting its goals. Shapiro and Astin (1998) developed "control therapy" as an integrated approach to psychotherapy, health, and healing, and advocate using this type of therapy to increase a person's sense of control. The positive health benefits that typically occur for participants who engage in some form of cognitive-behavioral therapy are often mediated by an increase in control-related beliefs. Providing patients with

greater control over some aspect of their health care delivery—for instance, by giving them increased information about what will happen to them and why, or by giving them choices over some aspect of their care—has been shown to lead to lower distress and faster recovery (Wallston, 1989). Sinclair, Wallston, Dwyer, Blackburn, and Fuchs (1998) showed that women with rheumatoid arthritis who underwent mastery effectiveness training increased their sense of control and psychological well-being.

## Desire for Control

Perception of control should not be confused with desire for control, a motivational construct. Most individuals would like to have control over their health status, but this is separate and distinct from whether they feel they have such control (Wallston, 1989). Not everybody wants to have control over their health care, even if they have an internal locus of health control orientation. Without a concomitant sense of self-efficacy or health competence, many individuals prefer to leave control of health care up to physicians and other expert health care providers, such as nurse practitioners.

## COST-EFFECTIVENESS

---

The term *cost-effectiveness* has been used in a number of different contexts and can have a number of different intended meanings. In the broadest sense, the term *cost-effectiveness* has been used to describe whether the value that something produces is worth what it costs. For example, a person may state that it was cost effective to hire a new employee because the new employee's productivity has increased revenues.

In the context of health and behavior, cost-effectiveness can also be used broadly or more specifically. In the broader sense, it describes the methods and results of a group of analyses that compare how much a health investment or intervention costs with how much health value it produces. When used more broadly, health value or health benefit may be measured in many different types of units such as

reduced mortality, dollars saved, or increase in health utility. In the more specific sense, cost-effectiveness analysis is one of a variety of methods for assessing the cost-effectiveness of a treatment. Other methods in this group include cost-benefit analysis, cost-utility analysis, and cost-offset analysis. The identifying characteristic of cost-effectiveness analysis is that health value or benefit is measured in terms of clinical care units such as lives saved, amount of blood pressure reduced, or increased scores on a questionnaire.

Admittedly, this distinction between similar terms can be confusing. The following example is provided for further clarification. Suppose a group of researchers design an exercise-based intervention for people with chronic illness. Participants attend weekly exercise classes over the course of 1 year. The researchers measure a variety of variables (demographic, psychosocial, physiological, health-related quality of life [HRQOL], health care utilization, and mortality) before and after the intervention. The researchers also measure and/or estimate how much it costs to conduct the intervention. Suppose the intervention works well and the researchers find that participants in the intervention group have less pain, less depression, higher HRQOL, lower health care costs, slightly lower mortality, and more exercise-related injuries than the control group. In addition, one of the researchers' previously stated objectives was to measure the cost-effectiveness of the intervention. Here, the term is being used broadly, and does not specify the exact method the researcher would use. Since the researchers have measured a variety of outcome variables, they could do a cost-benefit analysis, cost-utility analysis, cost-offset analysis, and/or cost-effectiveness analysis. Any or all of these specific methods would provide a gauge of how cost-effective the intervention was in a general sense. If cost-effectiveness analysis was used, the remainder of this entry is relevant. First, I give a brief background of how and why cost-effectiveness became important in the field of health and behavior. Second, I provide more detail on terms and specific analysis methods, followed by a list of important parameters to consider when conducting or evaluating an analysis of cost-effectiveness. Finally, I provide a brief discussion and summary about how the results of cost-effectiveness analyses are used in health policy and how the field of behavioral health and medicine can use cost-effectiveness in the future.

## BACKGROUND

The cost of health care in the United States has increased dramatically in the last 30 years and continues to increase both in total dollar expenditures and as a percentage of gross national product. Although there was a temporary slowdown in the early 1990s, the rate of increase began to accelerate again within a few years. When compared with other countries, the United States spends far more on health care (as a percentage of gross domestic product) than any other country in the world. However, the high expenditures do not appear to translate into better health. Among 13 countries in one recent comparison, the United States ranked 12th when compared on 16 different indicators of health. Therefore, improving the overall health of the population while containing costs has become a major objective for both U.S. researchers and researchers in most industrialized nations.

The main problem facing any health care system is that health care resources (dollars for spending) are limited, yet there is an almost unlimited demand to spend more on new treatments or diagnostic procedures. Health care providers want to do everything they can to help each individual patient, and there are numerous treatment options, including new, expensive technologies, but someone must pay for all of them. Currently, this usually means that some type of health insurance or government agency pays for the treatment, although costs are passed on to everyone through premiums and taxes. Therefore, the administrators of these large organizations must decide what are the best treatments for the money. In theory, by maximizing the amount of health gained for each given dollar, or conversely, by minimizing the amount spent for a given unit of health benefit, society receives the most health for the least amount of money. One unfortunate but unavoidable result of this is that not everyone can have all the health care they desire, and the cost of some treatments are not reimbursable.

For example, imagine that the amount that can be spent on health care is fixed at \$100,000, and \$5,000 of each \$100,000 (5%) is devoted to behavioral services. If behavioral health professionals are able to convince health administrators that their services deserve \$8,000 of each \$100,000 spent, there will naturally be less to spend on other nonbehavioral health services. This is called the opportunity cost problem. Opportunity costs are the foregone opportunities that

**Table 1** Comparison of Cost-Effectiveness, Cost-Utility, Cost-Benefit, and Cost-Offset Analysis

<i>Type of Analysis</i>	<i>Compares</i>	<i>To</i>	<i>Comments</i>
Cost-offset	\$ value of resources used	\$ value of costs reduced by the intervention, usually health care costs	Focuses on saving money instead of health improvement
Cost-benefit	\$ value of resources used	\$ value of all resources saved or created, including health and longer life	Places monetary value on health and lives
Cost-effectiveness	\$ value of resources used	Health effects: illness specific, limited in scope (blood pressure, mortality)	Not comprehensive Difficult to compare across diseases
Cost-utility	\$ value of resources used	Health effects: preference-based (health-related quality of life, QALYs).	Comprehensive Allows for comparisons across all groups studied

are relinquished when resources are used to pay for a particular decision or treatment. If a lot of money is spent on pharmacological services, for example, less money is available to be spent on other services such as preventive or behavioral services.

When confronted with the choice between two good programs, it is always tempting to support both, despite the increased costs, and this option has been used quite often in the past. However, now that health care costs have almost doubled in the last 30 years, employees and employers do not want their fees for health insurance to rise anymore and taxpayers do not want tax increases.

How do we decide which services should get more and which should get fewer resources? By examining the ratio of what treatment costs to how much health it provides and then comparing this ratio to that of other treatment options. As mentioned above, there are a number of different methodologies for doing this. These methodologies are described in detail in the following section in an attempt to remove ambiguities arising from their incorrect and/or interchangeable usages.

## TYPES OF COST-EFFECTIVENESS ANALYSIS

The terms *cost-offset*, *cost-benefit*, *cost-effectiveness*, and *cost-utility* are often used inconsistently in the health care literature. This is primarily because the methodologies are relatively new and have undergone changes and improvements with time. These terms may be used to describe a type of analysis, as in conducting a “cost-utility analysis,” or they may describe

a value or ratio such as a “cost-benefit ratio.” The key concepts are summarized in Table 1.

Some interventions claim that their results show a *cost-offset*. Cost-offset is a term used to describe interventions that save money independent of their health benefits. Most often, this savings is related to reduced health care utilization and health care costs. This approach measures both program costs and treatment outcomes in dollar units. For example, treatment outcomes may be evaluated in relation to changes in the use of medical services or the economic productivity of patients. Treatments produce a cost-offset if the economic return exceeds treatment costs. Patients with heart disease who are aggressively treated with surgery, for example, may need fewer emergency medical services and less medications. The savings associated with decreased services might exceed treatment costs. Sometimes investment in a service can save money. For example, investment in a behavioral psychotherapy program may reduce overall use of health services (Spiegel, 1999). The overall expense for those paying for health services is improved because there has been a cost-offset. A cost-offset may be present within cost-benefit or cost-effectiveness analyses but often shifts the focus away from whether the intervention improves health. Therefore, cost-offset is not recommended as the primary goal of intervention development.

Cost-benefit analysis is similar to cost-offset analysis in that both methods compare the cost of a treatment in dollars to the resulting outcomes in dollars. However, a requirement of cost-benefit analysis is that all outcomes have a dollar value attached. Therefore,

side effects of a medication or functional benefits from a surgery must have a dollar value placed on them. The health improvements and/or reductions in health must be evaluated in terms of a dollar figure. This poses a variety of problems, since many people are uncomfortable placing monetary values on human life. In addition, the requirement that health care treatments reduce costs may be unrealistic. Health consumers are willing to pay for better health just like they are willing to pay for other consumer goods and services. Health problems are not treated in order to save money. In fact, not treating patients at all is probably the least expensive approach. Treatments are given in order to achieve better health outcomes. Therefore, treatments should be evaluated in terms of their effectiveness, not just their financial outcomes. The methodologies used to accomplish this are cost-effectiveness analysis and cost-utility analysis.

Traditional cost-effectiveness analysis compares the cost of an intervention or treatment (the numerator) to how much health improves (the denominator) as a result of the intervention or treatment. In the past, the health improvement usually focused on one outcome or measure of health such as blood pressure, depression score, smokers who quit, or mortality. The result of the cost-effectiveness analysis was stated as a ratio of dollars per outcome achieved. A behavior-based smoking cessation program could state that it cost a certain amount for each smoker who quit smoking, and this could then be compared with other smoking cessation programs. However, there were two main problems with this methodology. First, side effects, whether they be positive or negative, were either not measured, or if measured, were not included in the cost-effectiveness results. When comparing the behavioral-based smoking cessation program with a medication-based smoking cessation program, there may be various side effects related to each intervention that are never measured. The medication may produce severe headaches and nausea, while the behavioral program results in some additional health benefit not associated with cessation. Neither the positive nor negative side effect of the intervention would be represented in the analysis.

Second, the cost-effectiveness of the program could not be directly compared to programs that targeted health issues besides smoking. This is a problem because health care administrators often can only fund a limited number of programs at a time because of budget constraints and have to choose between two or

more programs that target different health problems. For example, should the limited amount of money available be used to support tobacco cessation programs for all enrollees or should it be devoted to inpatient care for a few individuals? For a similar cost, the programs may achieve a large effect for a few people versus a smaller effect for a large number of people. In summary, the treatment-specific outcomes used in cost-effectiveness studies do not allow direct comparisons across different health conditions.

These two problems with cost-effectiveness analysis led to the concept of measuring health-related quality of life (HRQOL) and cost-utility approaches. Therefore, cost-utility analysis can be considered an improved subtype of cost-effectiveness analysis. It still expresses the results in terms of dollars per unit of health benefit, but improves upon older methodology by expressing the health benefits in a comprehensive manner and in units that can be used across all diseases or health states.

This could lead some to ask, What units are relevant to all health states? Cost-utility approaches use the preference or utility of a health state or treatment effect as the unit of outcome. Therefore, a large, representative sample of a population assigns values, preferences, or utilities to various health states that range from death to perfect health, and the average preference or utility of the sample is calculated for each measurable health state. These utility or preference weights can be multiplied by time spent in that state to calculate a quality adjusted life year or QALY (Kaplan & Bush, 1982). QALYs are the comprehensive, common unit that can be calculated for all health states and used in cost-utility analysis. Mortality is also included in these analyses, since death is assigned a utility score of zero. Perfect health, or a health state in which a person has optimal functioning and reports no health symptoms, is assigned a utility score of 1.0. All other health states are typically rated on a scale that ranges from 0 to 1.0. Many people believe there are health states worse than death, and have proposed negative utility scores, which are beyond the scope of this entry.

Thus, QALYs can be calculated as change in health utility scores over time multiplied by the preference or utility score from a utility-based quality of life measure. QALYs can be assessed using a number of validated questionnaires such as EuroQol 5D, the Health Utilities Index, and the Quality of Well-Being (QWB) Scale. Quality of life measures such as the SF-36, or

PedsQL (for children), are more descriptive quality of life measures from which utility or preference scores cannot be directly calculated. For example, if a self-management intervention for people with chronic illness found that the mean QWB score for the intervention group increases from 0.650 at baseline to 0.750 after 1 year of the intervention, and that the mean QWB score for the control group stayed at 0.650 for the year, there would be an increase of 0.10 QALY for the intervention group. Next, if the intervention had an average cost of \$500 per participant, the cost-utility ratio would be  $\$500/0.010 \text{ QALYs} = \$5,000/\text{QALY}$ .

### IMPORTANT CONSIDERATIONS FOR CONDUCTING COST-EFFECTIVENESS ANALYSIS

As with many fields of research, cost-effectiveness analysis has evolved over time, and a variety of methods, approaches, and terminology have proliferated. Scientific advances were promoted by some and opposed by others, resulting in difficulty when comparing results derived from different methods. Because of the heterogeneity of methodologies, in 1993 the federal government appointed the Panel on Cost-Effectiveness in Health and Medicine to develop recommendations for consistent practice of cost-effectiveness analysis. The goal was to create common standards that researchers from all health disciplines could implement and understand. The findings of the panel were published as a book (Gold, 1996) and in a series of papers (Russell, Gold, Siegel, Daniels, & Weinstein, 1996; Siegel, Weinstein, Russell, & Gold, 1996; Weinstein, Siegel, Gold, Kamlet, & Russell, 1996). In the following sections, important elements of good cost-effectiveness analyses as defined by the panel are briefly reviewed.

#### Perspective

Each cost-effectiveness analysis is conducted from a specific perspective, which should be clearly stated. An *individual* perspective considers only the costs and benefits of a program for an individual citizen or patient. An *administrative* perspective evaluates cost-effectiveness as it pertains to a specific organization or agency. From the *societal* perspective, all health benefits and associated costs are considered, regardless of who experiences them or pays for them. Results may differ dramatically as a function of perspective.

A health insurance company, for example, might save money by not covering certain interventions. Costs may be reduced from an administrative perspective, but from a societal perspective, costs could remain unchanged or even increase because other agencies would end up paying for this service or for the consequences of conditions being left untreated. The Panel on Cost-Effectiveness recommended using the societal perspective because they believed that fair decisions must take all parties into consideration. In addition, the societal perspective attempts to measure all possible impacts of an intervention, both positive and negative, making it the most complete and informative.

#### Effectiveness Measures

In the past, and as discussed above, cost-effectiveness analysis relied upon calculating how much it cost to produce a prespecified change in some disease-related health indicator such as blood pressure, weight loss, and lives saved. The need for more comprehensive measures of health that could be expressed in a common unit of measurement led to the development of the concept of QALYs and cost-utility analysis. The Panel on Cost-Effectiveness studied different options and recommended that all studies of cost-effectiveness measure and report outcomes in \$/QALY if possible. Hence, all effects of a treatment or intervention, whether they are physical, psychological, or behavioral, are measured and translated into one score and one ratio that can be compared across many diseases and populations.

#### Accounting for Costs

When studying cost-effectiveness from the societal perspective, as is recommended, it is important to consider all resources directly required for the intervention as well as any indirect costs that result. Side effects may arise from the treatment, which require additional resources to treat. Some other indirect costs include the value of the time spent in the intervention for participants, travel expenses for participants, impacts on family members or caregivers of the participants, and changes in productivity due to disability or premature death. Some of these costs may be captured as part of the comprehensive measurement of QALYs, but those that are not should be added into the numerator or cost side of the cost-utility ratio (\$/QALY).

## Discounting Costs and Outcomes

Empirical evidence suggests that future benefits are worth more in the present and that future costs are worth less in the present. For example, most people would choose to receive \$100 today versus \$100 1 year from today because they have an extra year to either invest that money or spend it on things they can enjoy sooner. Economic theory assumes that health is a commodity like money and that people prefer good health sooner and worse health later. To account for this principle, future health (like costs) is discounted. Although there is still debate about discount rates and whether health is valued in the same way as money, the Panel on Cost-Effectiveness concluded that for the purposes of standardization, health outcomes should be discounted at the same rate as monetary costs. They recommend a discount rate of 3% per year.

## Comparators

Calculating a cost-effectiveness ratio for an individual program by itself does not say much. The results of a cost-effectiveness analysis should be compared to that of an alternative intervention or program, such as a control group, or different intervention and the difference between the two ratios reported. A *comparator* is the alternative to which a new treatment is compared. The cost-effectiveness panel recommended that new treatments should be compared to the best alternative that would typically be used if the new treatment was not available. Often, the best available treatment is what is currently being done. Many studies compare the cost-effectiveness for the treatment only in comparison with the control group. The problem with this approach is that if a new treatment were not available, patients might seek an alternative treatment or remedy. Therefore, a no-cost control group may not be the best comparator.

## Time Horizon and Modeling

A time horizon refers to how long after the intervention costs and outcomes are assessed. In general, the longer that follow-up assessment continues, the better, since there is always the possibility for side effects or benefits in the future. However, it is impractical and costly to try to measure these variables indefinitely. This problem gave rise to the development of a more recent technique for extending the time horizon of a cost-effectiveness analysis by modeling or

estimating future outcomes. Computerized modeling techniques use estimates of the probability of the possible health outcomes to calculate the health consequences as well as the future costs of the intervention.

## Sensitivity Analysis

Sensitivity analysis is a statistical technique that is important for producing a high-quality evaluation of cost-effectiveness. Because almost every analysis of cost-effectiveness must estimate certain aspects of costs or rates of outcome, uncertainty remains based on estimated values. Sensitivity analysis explores how the results of the analysis would change if the estimates were varied between a realistic upper and lower bound. Therefore, studies should report how sensitive their results are to the estimates contained in their analysis.

## Cost-Effectiveness, Public Policy, and Other Issues

Now that the terminology and key methodological components of high-quality cost-effectiveness studies have been explained, it is important to consider how this information will be used. In general, health care administrators in private industry and in government must decide what treatments will be covered by insurance and what treatments will not. They must also decide whether to fund existing or new programs that promote health or prevent illness. Although individual health care consumers or providers can become outraged when their own health procedure is not covered, the reality is that health care costs would grow uncontrollably if every possible treatment and public health program were funded. Health care costs would increase dramatically for everyone since a large majority of U.S. health care is paid for by insurance premiums or government health programs (taxes).

Therefore, policymakers have the unenviable task of comparing many different health treatments and deciding whether they should be covered or funded. The reason for using the results of cost-effectiveness analyses is to provide an objective method to assess how to obtain the most health for society as a whole, given a limited budget. It is true that this is not the only factor driving these decisions. Surgeries that can save a life are not discontinued because they are relatively expensive when compared to a new behavioral prevention program. Instead, the cost-effectiveness methodologies are simply one important component of these policy decisions.

In behavioral health, cost-effectiveness methodologies have been underutilized when compared with medical research (Kaplan & Groessl, 2002). Even though a greater number of high-quality cost-effectiveness analyses are being conducted in behavioral health and medicine since the Panel on Cost-Effectiveness published their recommendations, considerable challenge remains for behavioral health researchers to adopt these new recommendations and demonstrate that behavioral interventions are cost effective and worth adopting. Additional reading on the subject of cost-effectiveness can be found in the readings below and literature cited within them.

---

## CROWDING AND HEALTH

---

The idea that close living quarters facilitates the spread of disease has long held sway in popular

opinion and among public health officials. There are at least two reasons to suspect why crowding might play a role in physical health. First, the probability of contamination from infectious diseases is higher when people are in close physical proximity to other individuals. Second, considerable evidence indicates that crowding is a stressor (Evans & Cohen, 1987; Evans, 2001) and thus might suppress immune function. Several important psychosocial processes, including negative affect and conflict, social support, and self-efficacy, are influenced by crowding. Thus, there are good reasons to suspect that crowding may also elevate risk for psychological distress. Below we discuss the measurement of crowding and evidence for physical and mental health sequelae.

### MEASUREMENT

How crowding is measured makes a difference in determining its health impacts. External indices of density such as people per census tract or people per square mile have little or no impact on human health. The salient experience of crowding is indoors, where people's activities are interfered with by the close presence of others (Stokols, 1972) and when crowding makes it difficult to regulate social interaction (Altman, 1975). Thus, indices such as number of people per room and to a lesser extent people per square meter are better metrics for the assessment of crowding health effects. People per room is the most sensitive index, probably because it best captures the underlying processes of behavioral constraint and unregulated social interaction that appear to convey the harmful impacts of crowding upon human beings.

### CROWDING AND PHYSICAL HEALTH

General population studies reveal mixed results when investigating associations between density and morbidity. Closer examination shows that among captive populations (e.g., schools, prisons, military, refugee camps), more consistent, although modest, associations are uncovered (Cox, Paulus, McCain, & Karlovac, 1982; Evans, 2001). Unfortunately, many population health studies are fraught with methodological and statistical difficulties. Some problems lead to potential overestimation of health effects such as reliance on cross-sectional designs, often without statistical controls for socioeconomic status. Other limitations can lead to underestimation bias. For

example, many studies use samples with restricted variance in residential crowding levels. Furthermore, we have little dose response data on crowding and health, and no human studies have examined immunological function and morbidity in the same sample. On the other hand, there are a few longitudinal replications of cross-sectional crowding-health associations, and some investigators have compared infectious to noninfectious disease rates and shown that only the former are related to crowding. There is also converging evidence from several crowding studies of institutional infirmity visits data with self-reports of physical symptoms.

Underlying physiological processes with documented links to physical morbidity are affected by crowding. Both laboratory and field studies reveal small but consistent elevations in psychophysiological parameters (e.g., skin conductance, blood pressure, catecholamines, cortisol) indicative of stress (Evans, 2001). Animal models suggest that some of these neuroendocrine changes also diminish fertility, providing a natural population regulation feedback mechanism. Efforts to uncover a human analogue have proven unsuccessful.

## CROWDING AND MENTAL HEALTH

Epidemiological evidence for crowding as a risk factor for mental illness is weak. Results are mixed, nearly all are cross-sectional, and some studies have inadequate controls for SES. Many crowding and mental health studies examine external density (e.g., people per census tract) rather than interior measures of density, and several rely upon relatively insensitive indices of mental health (e.g., psychiatric admission rates) (Gove & Hughes, 1983). Studies examining residential density and less catastrophic outcomes such as symptoms of anxiety and depression provide a more consistent pattern of evidence, although most are cross-sectional in design (Evans, 2001). Lepore, Evans, & Schneider (1991) are noteworthy in showing prospective evidence for an association between people per room and a standardized index of psychological distress.

Several psychosocial processes with well-documented mental health implications have been directly linked to residential crowding. These include experiences of negative affect or mood, interpersonal conflict, social withdrawal and diminished social support, and diminished feelings of self-efficacy or mastery

(Baum & Paulus, 1987; Evans, 2001; Gove & Hughes, 1983).

Both laboratory experiments and community studies consistently find links between crowding and negative affect or mood (Baum & Paulus, 1987; Evans & Cohen, 1987). Parent-child conflict is elevated in crowded households, and overt aggression may occur under certain circumstances. As one example, crowded nursery school children manifest more conflict when inadequate supplies of toys are available (Rohe & Patterson, 1974; Smith & Connolly, 1977).

Two programs of research have uncovered evidence that crowding leads to the deterioration of social support, which in turn elevates psychological distress. Baum and his colleagues in a series of studies in college dormitories have found that more crowded students are more socially withdrawn as evidenced by multiple indicators (Baum, Gatchel, Aiello, & Thompson, 1981). In several of these studies, students were randomly assigned to resident halls. Evans and Lepore have found both cross-sectionally and prospectively that residents of higher density homes have greater psychological distress that is mediated by diminished social support (Evans, 2001). People in crowded living environments appear to cope with too much unwanted social interaction by avoiding social contact. Unfortunately, an unintended side effect of this coping process is impaired social support, which in turn leads to heightened psychological distress. High-density living environments are evaluated as interfering with behavioral options and are associated with both self-report and overt behavioral evidence of diminished control beliefs. The latter includes laboratory and field evidence that persons in more crowded environments have deficits in motivation in achievement situations, such as working on a challenging puzzle (Baum & Paulus, 1987; Evans, 2001).

## SUMMARY AND CONCLUSION

Crowded interior living conditions are associated with infectious diseases among institutionalized populations. Crowding data for the general population do not support a clear link with physical morbidity. Both laboratory and field studies show elevated psychophysiological stress in relation to more crowded conditions. Social withdrawal and social support, beliefs that one has a sense of control over the environment, and under certain circumstances, conflict and aggression, are all impacted by crowding. Mental

illness is probably not affected by crowding, but psychological distress appears to be elevated by high-density interior living conditions.

Future research priorities on crowding and health include prospective, longitudinal studies, preferably with dose response data, that incorporate both underlying physiological processes (e.g., immune functioning) and physical morbidity. Parallel research is needed for psychosocial processes and psychological health outcomes.

## CULTURAL FACTORS AND HEALTH

---

Education and socioeconomic status account for a significant portion of health disparities, yet there is much that is unexplained. Study of the culturally encoded protective and risk factors in health may improve our understanding. Culture is broadly defined as a set of guidelines regarding values, beliefs and attitudes, social roles, emotions, and behaviors for living. Culture may exact direct (e.g., limited English proficiency decreases health access) and indirect (e.g., self-efficacy as modifying or mediating preventive behaviors or adherence) effects upon health. The influence of cultural factors has been documented for coronary heart disease, cancer prevention, pain, mental health, suicidal behavior, health cognitions and behavior, emotions, health communication, help-seeking, and health decision-making strategies.

### ACCULTURATION, COMMUNICATION, AND LANGUAGE

The study of cultural factors in health is difficult because it is a moving target, undergoing continual change (across individuals, families, and through historical time) by socialization, acculturation, and social stratification (e.g., age, gender, or social class). In order to maximize health, people must retain healthy lifestyle practices from the culture of origin (plant-based diet with few processed foods) and adopt healthy lifestyle practices from the new cultural environment (health screening and preventive behaviors).

Language is a very basic aspect of culture. Having limited proficiency in using the language of the adopted country hinders health access, creates health professional/patient miscommunication, and decreases efficacy of English-only health promotion strategies, and leads to health disparities. We are only beginning to understand the influence of culture in health communications (visual-explicit levels to the implicit, emotional, and symbolic meanings). Cultural factors influence learning processes, cognitive information processing, and motivational strategies, especially

when new healthy lifestyles must be learned to replace unhealthy lifestyles.

## PERCEPTIONS OF HEALTH AND ILLNESS

There are differences in how cultures view the human body (optimal shape, size, construction, how it functions, boundaries), their prescriptions for health maintenance, perceived causes and resulting treatment of bothersome health conditions, and maintenance of well-being. Many cultures around the world have a more holistic view of health and wellness—an integration of the mind, body, and spirit. Western medicine (biomedical model of health) takes into account principles of physiology, anatomy, and biochemistry. People who view health more holistically express greater dissatisfaction with the quality of health care within a biomedical model of care. The congruence between culturally based lay models and medical models of health and illness have implications for health care and satisfaction.

The most globally held lay concept of health is the humoral theory, with roots in ancient China and India, elaborated by Hippocrates but abandoned by Western medicine. Under this belief system, health is achieved when the four humors (i.e., blood, phlegm, yellow and black bile) are balanced; ill health comes from an imbalance of these humors. Health interventions to regain balance come from food, herbs, medicine, spiritual or divine, social or environmental sources. Even in the context of strong cultural health beliefs, culturally responsive health education has been effective in promoting healthy behaviors (e.g., health screening, physical activities, nutrition), at least on a short-term basis. Long-term maintenance of healthy behaviors is a struggle for most people but may be more difficult if they are foreign to one's cultural beliefs.

## PERSONALITY, STRESS, AND COPING

Cultural syndromes are organized themes around shared attitudes, values, beliefs, norms, social roles, and self-definitions. There are four attributes that define individualism-collectivism (Triandis, 1996): (1) meaning of the self as independent (individualistic) versus interdependent (collectivistic), (2) structure of goals as priority to in-group goals (collectivistic) versus personal goals (individualistic), (3) behavior as a function of norms (collectivistic) versus attitudes (individualistic), and (4) focus on in-group needs

(collectivistic) or social exchanges (individualistic). Differential health outcomes have been associated with individualistic societies, higher smoking and cardiovascular heart disease, higher suicide, and psychological well-being rates when compared to collectivistic cultures.

Self-efficacy (e.g., internal locus of control, John Henryism, active coping) is a belief in one's own ability to effectively influence outcomes and is related to greater health promotion involvement, utilization of health screening, and better blood pressure control. In collectivist cultures, powerful others (family, friends, or health professionals) have a more prominent role in influencing health outcomes.

Cultural groups have different clusterings of stress symptoms and protective factors such as family cohesion, and hold different worldviews about the role of human suffering that may buffer or moderate the negative effects of stress. Cultures typically provide scripts and strategies such as meditation or mobilizing of social support networks to deal with life's miseries. Strong cultural beliefs may have negative implications for health such as difficulty in coping with a new culture and adoption of smoking or drinking to relieve stress.

## HELP-SEEKING BEHAVIORS AND HEALTH DECISION MAKING

Culture shapes the *who* (self, faith healer, medical doctor), *what* (influenza, germs, spiritual possession, curse), *when* (tomorrow, next week, month, or when other family needs have been met first), *where* (at home, community, doctors office or emergency room) of health, and *how* of help seeking, expectations for health care, and health decision making. For instance, a diagnosis of cancer may mean "immediate and certain death." Fears and anxiety regarding cancer have been associated with low clinical breast and Pap tests among minority women. Embarrassment may result during breast or Pap screening performed by male health professionals because of culturally based gender role expectations among older Asian immigrant women. Asians and Hispanics view Western medicines as very potent. They are cautious about their side effects and may decrease the dosage or abruptly stop taking the medication when they feel better. When patients ascribe high authority to healers (e.g., medicine man or medical doctor), suggestions by that healer to engage in health promotion behaviors may

have more influence in encouraging that behavior. Social support and social ties are predictive of mammography use in African Americans. In other words, cultural characteristics can be used to encourage health promotion and decrease health-damaging behaviors.

In summary, culture shapes how people view health and illness, influences how people feel about their health and how people will deal with life's stressors, and guides their help-seeking behaviors and health decision-making strategies. Cultural factors have been found to influence many aspects of health.

## DEPRESSION: MEASUREMENT

---

The measurement of depression is dependent upon the thoughts, feelings, and behaviors that are assumed to define this disorder (Beck, 1967). Consequently, the various instruments that have been developed to screen people in general for depression or measure the severity of depression in patients who have already been diagnosed with psychiatric disorders may stress different behavioral signs and self-reported symptoms. For example, the Beck Depression Inventory FastScreen for Medical Settings (Beck, Steer, & Brown, 2000) and the Geriatric Depression Scale (GDS; Yesavage, Brink, Rose, Lum, Huang et al., 1983) do not contain any somatic symptoms of depression, such as loss of appetite, that might be attributable to medical problems.

Most scales of depression are internally consistent, yield scores that are moderately stable over time, and are positively associated with other measures of depression (for comprehensive reviews of specific scales, see Beckham & Leber, 1995; Marsella, Hirschfeld, & Katz, 1987; Reynolds, 1994; Sartorius & Ban, 1986; Yonkers & Samson, 2000). However, measures of depression have also been repeatedly found to be related to other measures of psychopathology, such as anxiety scales (Clark & Watson, 1991), and approximately 50% of what is being measured by a depression scale may represent general symptom distress or negative affectivity (Steer, Clark, Beck, & Ranieri, 1999).

There are two basic types of measures of depression: (1) clinical rating scales, such as the

Hamilton Psychiatric Rating Scale for Depression (HRSD; Hamilton, 1960), the Montgomery-Asberg Depression Rating Scale (Montgomery & Asberg, 1979), which was derived from the HRSD, and the Three-Area Severity of Depression Scale (Raskin, 1988), which permit a clinician to rate observable behavioral signs of depression, such as psychomotor retardation, and (2) self-report instruments, such as the amended Beck Depression Inventory (Beck & Steer, 1993), the Center for Epidemiologic Studies Depression Scale (CES-D; Radloff, 1977), and the Zung Self-Rating Depression Scale (SDS; Zung, 1965), which rely upon a respondent's awareness and willingness to describe symptoms. Although clinical rating scales and self-report instruments may stress different aspects of depression (e.g., the HRSD contains more somatic symptoms than does the BDI), both types of scales can usually be scored for subscales that permit comparing a person's cognitive, affective, and somatic aspects of depression with one another.

Some depression scales, such as the GDS, are composed of questions for which yes or no answers are requested, whereas other scales, such as the CES-D, ask respondents to describe how frequently each item in a list of symptoms has occurred using a rating scale that might range from *Never* to *All of the Time*. In contrast, the BDI, which is the most widely used instrument for measuring the severity of depression in adolescents and adults (Piotrowski, 1996), requests that respondents (a) read groups of statements about a specific symptom that are listed in terms of increasing severity and then (b) select the one statement in each group that best describes how they have been feeling.

The lengths of time upon which the ratings are based may also vary. One instrument might question about feelings for the past month, whereas another scale might inquire about present feelings. The former instrument is measuring depression as an enduring trait, whereas the latter instrument is evaluating depression as a transient state or mood.

There are a variety of measures that now address the symptom criteria for depressive disorders that are listed in the *Diagnostic and Statistical Manual of Mental Disorders*. For example, the clinical rating and self-report scales in the Inventory of Depressive Symptomatology (Rush, Giles, Schlesser, & Fulton, 1985), the Hamilton Depression Scale (Reynolds & Kobak, 1995), which is a self-report version of the HRSD, the Beck Depression Inventory-II (BDI-II; Beck, Steer, & Brown, 1996), which is the upgraded version of the amended BDI, and the Depression Inventory for Youth (Beck, Beck, & Jolly, 2001) specifically address symptoms corresponding to *DSM-III-R/DSM-IV* depressive disorders. However, several widely used instruments, such as the Children's Depression Inventory (CDI; Kovacs, 1992), the Hospital Anxiety and Depression Scale (Zigmond & Snaith, 1983), and the Reynolds Adolescent Depression Scale (Reynolds, 1987), were not constructed to assess symptoms representing specific depressive disorders, and include symptoms, such as anxiety, that are associated with depression.

The HRSD, the BDI, the CES-D, the CDI, and the GDS have both short and long versions, and the symptoms listed in the HRSD and the BDI have changed over the years. The original version of the BDI (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) was only slightly rewritten to become the amended BDI. However, the amended BDI was substantially changed when it was upgraded to the BDI-II by adding several new symptoms and deleting several old symptoms from the original version. The original version of the HRSD had 17 items (Hamilton, 1960), whereas one of the most widely used versions of the HRSD contains 24 items (Guy, 1976). Unfortunately, it is sometimes difficult to ascertain which version of an instrument has been used, because only the original reference for an instrument has been cited, instead of the version that was actually employed.

Finally, many instruments assessing a broad spectrum of mental health symptoms contain scales of depression, such as the Multiple Affect Adjective Check List—Revised (Zuckerman & Lubin, 1998),

the Minnesota Multiphasic Personality Inventory-2 (Hathaway & McKinley, 1989), and the Symptom Check List-90-R (Derogatis, 1983). However, none of these measures of depression can be used by itself to diagnose clinical depression. A detailed structured clinical interview, such as that provided by the Structured Clinical Interview for *DSM-IV* (First, Spitzer, Gibbon, & Williams, 1996) or the Children's Interview for Psychiatric Syndromes (Weller, Weller, Rooney, & Fristad, 1999), is required to establish whether a person's symptoms meet criteria for a specific depressive disorder.

## DEPRESSION: MORTALITY AND OTHER ADVERSE OUTCOMES

---

The association between depression and mortality has been well established in both clinical studies and studies of community samples of adults. In clinical samples, the lifetime risk of suicide has been estimated to be as high as 15% for persons with unipolar or bipolar depression (though some question the magnitude of this risk). In addition, depression is known to increase the risk for nonsuicide mortality, especially mortality secondary to cardiovascular disease. The mechanisms by which depression leads to an increased risk for nonsuicide mortality, however, have yet to be determined and probably involve multiple, independent feedback loops, such as the association of depression and functional disability over time. The association of depression with suicide, nonsuicide mortality, and functional status are reviewed below.

## DEPRESSION AND SUICIDE

Suicide is the eighth leading cause of death in the United States, although the overall rate of between 11 and 12 per 100,000 annually has not changed appreciably over the past few decades. White males over the age of 65 as well as persons who live alone and are in poor health are at greater risk for suicide. The frequency for White males over 65 years of age is 62 per 100,000 per year. A history of depression can be identified in 50% to 75% of cases of suicide. The period of greatest risk occurs within 3 months of the onset of a depressive episode and within 5 years of the onset of a lifetime history of a major depressive disorder.

## NONSUICIDE MORTALITY

The association of depression and nonsuicide mortality has been extensively studied in both community and clinical samples. The relative risk for depression as a predictor of nonsuicide mortality varies from one (meaning no risk) to four, but most studies find about a twofold increased risk. The effect appears to be stronger in men than in women. Rates across race do not appear to vary (as they do for suicide). The risk may be higher in clinical samples of psychiatric patients than community-based samples.

There are many potential causes of the increased risk for mortality among persons with depression. Persons with depression may not comply with recommendations for their health care, such as taking medications regularly. In addition, the depressed are more inclined to smoke and exhibit other lifestyle characteristics (such as poor diet) associated with an increased mortality risk. They may, due to their depressive symptoms, be less likely to maintain an adequate social support network (and impaired social support has clearly been associated with an increased risk of mortality). In addition, depression may contribute to an increased biological vulnerability to disease, especially cardiovascular disease. The stress of a depressive episode may trigger episodes of transient cardiac ischemia. Other mechanisms that have been proposed include decreased vagal tone secondary to hypothalamic pituitary adrenal axis abnormalities, which leads to decreased heart rate and alterations in platelet serotonin receptors that may promote plate clumping.

The evidence for an association in the elderly, however, remains inconclusive, especially in well-controlled studies. These inconclusive results, which

derive especially from community-based studies, are probably secondary to which variables are controlled and which are not. For example, if an investigator controls for functional impairment, the risk for mortality secondary to depression decreases (often approaching unity). Depression is known to lead to increased functional disability, and functional disability, in turn, leads to an increased mortality risk. Functional disability also increases the risk for depression. Therefore, functional disability becomes a key mediating factor in the association of depression and mortality. How one conceives the interaction of depression and functional status over time will usually determine whether or not variables such as functional status are considered true confounding variables in the study of the association of depression and mortality.

## DEPRESSION AND FUNCTIONAL STATUS

Depression increases the risk for functional disability, perhaps as much as any chronic medical disorder such as diabetes or cardiovascular disease. Among the clinically depressed, as many as 17% may be unable to work because of their depression. Even less severe (or minor) depression is associated with increased disability days and days lost from work. Depression has been most often studied as a risk for disability among the elderly, increasing the risk for disability over 6 years by nearly 70%. Physical disability, as noted above, can also lead to depression, creating a vicious downward spiral. Functional decline can lead to restriction of valued social and leisure activities, increased social isolation, and a reduction in the quality of social support. Among the oldest old, the interaction of depression and disability may lead to the serious syndrome of frailty and failure to thrive and ultimately to death.

In summary, depression is a significant risk factor for a decline in physical health and functional status. These declines, plus more direct pathways, render depression a risk for increased mortality. Depression also is a risk for mortality directly through the increased risk for suicide.

## DEPRESSION: TREATMENT

---

Clinical depression refers to a group of psychiatric disorders in which the primary symptoms are persistent depressed mood (either self-reported or observed by others) and/or markedly diminished interest/pleasure in activities most of the day, nearly every day, for at least a 2-week duration (American Psychiatric Association, 1994). These psychiatric disorders are comprised primarily of Major Depressive Disorder (MDD), single episode and recurrent, and Dysthymic Disorder (DD). Although MDD and DD can co-occur, DD represents a less severe but longer lasting disorder marked by persistent depressed mood. The majority of individuals (approximately 72%) who have had MDD tend to have recurrent episodes of depression (Kessler, Zhao, Blazer, & Swartz, 1997).

To be diagnosed with MDD, the patient must have a number of psychological and physiological symptoms that represent a change from previous levels of functioning, that lead to significant impairments in functioning, and that cannot be attributed to the direct effects of a chemical substance, medication, or an existing medical condition (American Psychiatric Association, 1994). A number of significant individual differences can be present in the manifestation of MDD that may have an effect on the severity and course of depression. Psychologically, MDD may, but does not necessarily, involve feelings of worthlessness, diminished ability to concentrate, and recurrent thoughts of death. Physically, the depressed individual may experience weight changes (either gain or loss), sleep disturbances (too much or too little), restlessness, or psychomotor retardation. The fact that the symptom constellation that accompanies MDD can differ between depressed individuals suggests the presence of multiple etiologies for this disorder.

Consistent with the diverse symptom presentations possible in MDD, a number of treatment approaches, both psychological and pharmacological, have been developed. The focus of this entry is on the primary psychological and biological interventions studied and found to be efficacious in clinical trials of treatments for MDD. Efficacy in many of these studies was defined as a reduction of symptoms from one treatment relative to the effects of an appropriate control/comparison treatment and/or a 50% reduction of symptoms as assessed by standardized measures relative to baseline. It is important to note that while many theories and hypotheses exist, the underlying mechanisms that cause depression remain to be established empirically. Although many of the treatments to be described have been shown to be effective in reducing the symptoms of depression, none of these treatments can be considered to be a cure for depression.

## PSYCHOLOGICAL TREATMENT APPROACHES

Three psychotherapeutic approaches, namely cognitive, behavioral, and interpersonal, have attracted much of the research attention in clinical studies of depression. Although a number of specific psychotherapies fall under each approach, Beck's cognitive psychotherapy (CT; Beck, 1967), Klerman's interpersonal psychotherapy (IPT; Klerman, Weissman, Rounsaville, & Chevron, 1984), and Lewinsohn's behavioral psychotherapy (BT; Lewinsohn, Youngren, & Grosscup, 1979) have been

most studied and found to be empirically validated as efficacious treatments for depression (Frank & Thase, 1999). While both psychotherapies apply a time-limited, present-focused approach, the focus of the therapy is distinctive with each approach, based on theories postulating different core issues underlying the development and maintenance of depression.

### Cognitive Psychotherapy

According to the theory proposed by Beck in 1967, individuals who have relatively stable negativistic concepts and attitudes about themselves, the world, and the future are predisposed to developing depression. These negativistic concepts are believed to have developed over time through experience and are an organized cognitive structure, referred to as a schema. Schema is the pattern in which the environmental stimuli are cognitively broken down and organized into psychologically meaningful information. The negativistic attitudes take the form of value judgments individuals habitually makes about themselves, the world, and the future. The negative attitudes and schema are reflected in the dysfunctional automatic thoughts that have become the habitual manner of thinking for the depressed individual. In the presence of stressor(s) or difficult life situations, the negativistic attitudes associated with a maladaptive cognitive schema ultimately lead to depressed mood.

The maladaptive cognitive schema, believed to be maintained by cognitive errors, is hypothesized to have an adverse effect on the depressed individual's interpretation of experience. Six types of cognitive errors, namely, (1) arbitrary inference, (2) selective abstraction, (3) overgeneralization, (4) magnification and minimization, (5) personalization, and (6) absolutistic, dichotomous thinking, have been specified from the CT perspective on how depressed individuals may misinterpret a life experience (Beck, Rush, Shaw, & Emery, 1979).

CT, from Beck's perspective (Beck et al., 1979), is a didactic process in which the therapist teaches the depressed client to identify, recognize, and monitor negativistic automatic thoughts and cognitive errors. To increase the client's awareness of these maladaptive thoughts, a frequently employed homework assignment is to keep a log of automatic thoughts that occur. Once the automatic thoughts are identified, the therapist may use "if-then" and "what-if" types of questions to delve deeper into the underlying meaning

that these thoughts have for the depressed client to infer the cognitive schema. For example, an individual who often thinks that he or she will not be able to successfully overcome a problem as an initial response to a challenging situation may hold a more general belief that he or she is not intelligent, even though such a perception is not accurate. Once identified, the client is taught to objectively examine the automatic thoughts to determine if there is a basis in reality for the thoughts and to challenge the validity of the automatic thoughts within a collaborative therapist-client relationship. As therapy progresses, similar methods would be employed to examine and challenge the cognitive schema, the core belief system believed to underlie the depression.

### Interpersonal Psychotherapy

In the interpersonal theory of depression proposed by Klerman and colleagues (1984), the precipitating factor associated with the onset and perpetuation of depression is social maladjustment. According to this theory, impaired caretaker-child bonding in early childhood predisposes an individual to the development of impaired interpersonal relationships, which can trigger and/or foster depression in adulthood.

The overall goals of IPT are to reduce symptoms of depression and the four interpersonal problem areas associated with the onset and perpetuation of depression. In this time-limited psychotherapy, the strategy in the initial sessions is to identify the depression symptoms and to associate the depression to interpersonal issues that may be responsible for the depression. The primary interpersonal difficulties to be addressed in therapy are categorized into four problem areas, namely unresolved grief, interpersonal disputes, role transitions, and interpersonal deficits. Unresolved grief is addressed by facilitating the mourning process and by reestablishing interest in the development of new relationships. In resolving interpersonal disputes, the focus is on the modification of nonreciprocal role expectations or faulty communication patterns. Problems involving role transitions are ameliorated by encouraging acceptance of role loss, fostering a positive view of the new role, and developing a sense of mastery over the requirements of the new role through methods such as social skills training. Interpersonal deficits center on social isolation and the need to develop new relationships.

To meet these goals, IPT incorporates an array of diverse psychotherapeutic techniques, including relatively less directive psychodynamic techniques such as encouragement of affective expression in addition to more active means such as decision analyses, aimed at encouraging the patient to delay impulsive action and to consider a number of possible ways to solve an interpersonal problem.

### Behavioral Therapy

Lewinsohn's behavioral therapy (BT) (Lewinsohn et al., 1979) is a treatment approach that has been found to be effective in the reduction of depression (Antonuccio, 1998). The theory behind BT posits that the occurrence of a stressful situational or environmental event (e.g., job loss or ongoing marital discord) precipitates the chain of events that lead to the onset and/or maintenance of depression. These stressful events are thought to lead to a disruption of established behavior patterns and a reduction of pleasant events and/or an elevation of aversive events that may be associated with depressed mood, behavioral withdrawal, and self-criticism. The primary goal of this therapy is to increase the frequency of pleasant events and to reduce aversive events by altering the individual's activities and social interactions. The strategies used in this psychotherapy (Lewinsohn & Arconad, 1981) include changing the environmental conditions (e.g., increasing rewarding activities), teaching skills to enhance interactions with the environment (e.g., social skills training), and enhancing the pleasantness or decreasing the aversion of interactions with the environment (e.g., relaxation training and cognitive self-management such as thought stopping).

### BIOLOGICAL TREATMENT APPROACHES

The most common biological treatment approach for MDD is pharmacotherapy, which has been shown to be an effective treatment in a number of clinical trials. A less frequently employed but effective biological treatment for depression is electroconvulsive therapy, a method that is usually reserved for severe cases that do not respond to other mainstream treatments.

The development of pharmacological treatments for depression began in the 1950s and in the years following with the discovery that a monoamine oxidase inhibitor and a tricyclic compound, which were originally developed as antituberculosis and antipsychotic

agents respectively, also had mood elevating effects. Following a series of agents that were variants of these antidepressants, a significant advance in the pharmacotherapy of depression came in the late 1980s into the 1990s with the development of a new class of agents known as selective serotonin reuptake inhibitors (SSRIs), which lacked many of the potentially fatal side effects present in the two existing classes. More recently, a diverse group of novel agents has been developed that has a relatively favorable side effect profile and has been shown to be at least as effective as existing antidepressant agents.

Most antidepressant pharmacological agents are known to affect the monoamine neurotransmitters, which include epinephrine, norepinephrine, dopamine, and/or serotonin (5-HT). Neurotransmitters are chemicals that travel across the connective junctions of cells (i.e., synaptic junctions), enabling cells to communicate with each other. It is believed that the therapeutic effect on depression is due to the effects of the pharmacological agent on these neurotransmitter systems.

### Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) inhibit an enzyme, monoamine oxidase (MAO), found in the body as well as the brain, thereby increasing the availability of monoamine neurotransmitters. There are two known types of MAO enzymes (A and B). Type A MAO is relatively selective for the metabolism of 5-HT and norepinephrine, while Type B MAO is relatively selective for the metabolism of benzylamine and phenylethylamine.

The early MAOIs (e.g., phenelzine or Nardil and tranylcypromine or Parnate) were irreversible in the sense that the drug would bind to the MAO enzyme permanently and be nonselective in terms of binding to both types of MAO. These early MAOIs are not often prescribed at present due to potentially life-threatening side effects. A hypertensive crisis and possibly stroke can result from ingestion of food products containing relatively high levels of tyramine (e.g., cheeses). Potentially fatal drug interactions have been discovered among individuals taking early MAOIs along with stimulants, commonly used over-the-counter cold remedies, and other antidepressants. Other possible significant side effects of early MAOIs are weight gain, postural hypotension, sexual dysfunction, and hepatotoxicity, for which the original

MAOI, iproniazid, was withdrawn from use. Mortality from overdosing on early MAOIs has also been reported, raising concerns about prescribing this agent to severely depressed patients who may be at risk for suicide.

Many of these drawbacks of the early MAOIs were resolved with the relatively recent introduction of the reversible MAOIs (Lotufo-Neto, Trivedi, & Thase, 1999), such as moclobemide and brofaromine. Moclobemide is much less likely to produce a hypertensive crisis, as this drug is readily displaced from its binding site on the Type A MAO. This reversible MAOI has been found to be relatively safer in overdose situations and is not associated with orthostatic hypotension, although some common side effects include nausea, insomnia, tremor, and dizziness. Although this agent has been found to be more efficacious relative to placebo and as effective as tricyclic antidepressants and SSRIs (Lotufo-Neto et al., 1999), this agent is currently available only outside the United States.

### Tricyclic Antidepressants

The first tricyclic antidepressant (TCA), imipramine, was a tricyclic compound that was a structural variant of the antipsychotic agents known as the phenothiazines. The TCAs that followed imipramine include amitriptyline, clomipramine, desipramine, dothiepin, doxepin, lofepramine, and nortriptyline. Most TCAs are thought to block predominantly the reuptake of norepinephrine, although some agents (e.g., amitriptyline) also block the reuptake of serotonin and to a lesser degree dopamine.

The efficacy of TCAs has been well documented, and TCAs are often thought to be the most effective pharmacological agent for severe depression. A significant drawback to TCAs in general has been the potential for adverse cardiovascular effects of the drug. Postural hypotension, tachycardia, and arrhythmias have been found to occur with TCAs. Overdosing on TCAs has also been found to cause cardiac arrest. Other relatively common side effects include sedation, dry mouth, blurred vision, weight gain, and recent memory loss. Many of these side effects are associated with the anticholinergic effects, resulting from the inhibition of cholinergic neurotransmission at muscarinic receptor sites. TCAs vary in terms of the likelihood for anticholinergic effects; imipramine and amitriptyline are two of the more

highly anticholinergic TCAs. Despite these significant side effects, TCAs are considered to be the standard by which efficacy of other agents is compared.

### Selective Serotonin Reuptake Inhibitors

Unlike the TCAs, the selective serotonin reuptake inhibitors (SSRIs) are known to almost exclusively inhibit the reuptake of 5-hydroxytryptamine (5-HT), a neurotransmitter also known as serotonin, although the chemical structure of these antidepressants may differ. The inhibition of the reuptake of 5-HT following its release into the neural synapse increases the activity of serotonin in the central nervous system. Some of the most commonly prescribed drugs belonging to the class include citalopram (Celexa), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft).

In recent years, the popularity of the SSRIs has increased dramatically, mostly due to a favorable side effect profile, increasing the likelihood that the patient will be tolerant of and adherent to this medication. The SSRIs do not require the type of dietary restrictions of MAOIs and do not have the cardiovascular side effects of TCAs. Unlike the SSRIs and the TCAs, overdose on SSRIs alone is rarely fatal, reducing the potential for lethality in depressed suicidal patients. Sexual dysfunction and headaches are common adverse effects of some SSRIs, however.

### Current Generation of Antidepressants

While the SSRIs yielded more favorable side effect profiles, the need to increase the efficacy and the onset of therapeutic effects of these agents, among other issues, remained. In general, most available antidepressants produce remission of depression in only a fraction of patients (30%), with partial response (40%) and no improvement (30%) being the majority outcome (Gumnick & Nemeroff, 2000). The latest antidepressant medications are the result of attempts to bring about improvements in these areas. These include dual serotonin-norepinephrine reuptake inhibitors such as venlafaxine (Effexor), potent 5-HT<sub>2</sub> receptor antagonists such as nefazodone (Serzone), tetracyclic antidepressants such as mirtazapine (Remeron), the norepinephrine reuptake inhibitor reboxetine (not available in the United States), and bupropion. These agents have been found to be as efficacious as TCAs, and some evidence suggests that

venlafaxine and reboxetine may be more efficacious compared to SSRIs for the treatment of severe depression (Gunnick & Nemeroff, 2000). A variety of side effects have been noted in these agents, with the arguably most significant ones being a dose-dependent blood pressure increase for venlafaxine, drug interactions with benzodiazepines for nefazodone, weight gain and sedation for mirtazapine, and increased seizure risk for bupropion.

### Other Biological Treatments

In electroconvulsive therapy (ECT), an electrical impulse is applied either unilaterally or bilaterally to an anesthetized patient's head in order to produce a generalized seizure of approximately 1 minute in duration. The frequency and duration of this treatment vary significantly, depending on patient-specific issues, although a typical regimen can involve two to three sessions per week for several weeks.

ECT is thought to be beneficial for individuals with treatment-resistant depression and very severe MDD (e.g., extreme agitation, highly suicidal, psychotic, and/or severe neurovegetative symptoms). This procedure may be contraindicated, however, in patients with cardiovascular disease (e.g., hypertension, recent myocardial infarction), cerebrovascular disease, respiratory illnesses, brain tumors, and conditions involving increased intracranial pressure. Confusion and memory loss are relatively common adverse effects, which can be accentuated in older patients and patients receiving concurrent lithium pharmacotherapy and/or bilateral ECT administration.

### EMPIRICAL COMPARISON OF PSYCHOLOGICAL AND BIOLOGICAL TREATMENTS

The National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program was the first large-scale randomized placebo-controlled study to directly compare the efficacy of two prominent psychotherapies, Beck's CT and Klerman's IPT, as well as to compare psychotherapy with the antidepressant medication imipramine, plus clinical management (TCA condition), for the treatment of depression in 250 patients over a 16-week treatment period. At termination of treatment, patients in all four conditions showed similar mean improvement in depressive symptoms

(Elkin et al., 1989). Primarily on the basis of analyses of recovery rates (scores below a cutoff on depression rating scales), however, the authors concluded that imipramine was most effective and that the evidence for efficacy was limited in IPT and not at all evident for CT, especially among the more severely depressed patients evaluated shortly after treatment termination.

The results of Elkin and colleagues about the ineffectiveness of CT were at odds with previous meta-analyses that suggested CT was more effective than other psychotherapies and pharmacotherapies available at the time (Dobson, 1989). Follow-up analyses of pooled data from four studies (including the NIMH study), using more rigorous criteria for selection of studies, found no conclusive evidence that CT was different in efficacy from imipramine among severely depressed outpatients (DeRubeis, Gelfand, Tang, & Simons, 1999). Moreover, in the NIMH study, recovery rates (8 weeks of minimal/no symptoms and no MDD relapse) assessed at 6-, 12-, and 18-month follow-up evaluations were similar across treatment groups (Shea et al., 1992). Taken together, these studies suggest that no differences in efficacy exist between these psychotherapies and that psychotherapy and TCAs are equally efficacious for the treatment of depression.

Studies comparing TCAs and SSRIs for the treatment of depression support the use of SSRIs, and SSRIs have become the first-line pharmacological agent of choice for the treatment of depression (Petersen et al., 2002). Meta-analyses of efficacy studies comparing SSRIs and TCAs have found no significant differences (e.g., Anderson, 2000). In terms of discontinuation of therapy due to side effects, however, significantly less dropouts have been associated with SSRIs relative to TCAs, with the exception of fluvoxamine, which was similar to the dropout levels found for TCAs (Anderson, 2000).

Some recent studies of dual action antidepressants (inhibitors of both 5-HT and norepinephrine reuptake, e.g., venlafaxine) have suggested that these agents may be more efficacious than SSRIs, particularly for severe depression, and better tolerated than TCAs (Tran, Bymaster, McNamara, & Potter, 2003). These findings are equivocal, however, as other studies have reported no significant differences, and further study on the efficacy of dual action agents is warranted.

A recent review of clinical trials of ECT suggests that it is an effective treatment for depression relative to placebo and that it may be more effective than drug

therapy (UK ECT Review Group, 2003). No evidence was found in this review to suggest that ECT may cause brain damage, as detractors have suggested, although few studies have examined this issue. This method is not usually considered a first-line treatment, however, given the highly invasive nature of this technique.

Since much of the evidence on established treatments for major depression suggests similar degrees of efficacy, the choice of first-line treatment, both between and within types of treatment, remains heavily dependent upon an evaluation of clinical issues between the patient and the clinician (e.g., Gumnick & Nemeroff, 2000). These issues can include but are not limited to patient preferences for one treatment over another, severity of the illness, relapse pattern, tolerance or presence of side effects, previous treatment history, and the presence of comorbid medical or psychiatric disorders. Several treatment guidelines have been published to date (Trivedi & Kleiber, 2001; see Further Reading) that generally follow the principle of starting with the least invasive procedures with the most favorable side effect profile first (e.g., SSRIs, psychotherapy) and moving toward more invasive procedures if the patient is nonresponsive.

## DIABETES: BEHAVIORAL TREATMENT

---

Diabetes mellitus (DM) is a disorder of metabolism manifested by hyperglycemia. Type 1 and Type 2 are the primary types of diabetes. Although different in etiology, both types exhibit a high degree of comorbidity with other disorders, primarily hypertension and dyslipidemia. Long-term complications include microvascular, macrovascular, and neurological damage. The etiology of Type 2 DM rests squarely on behavior, particularly overeating, lack of exercise, and poor food choices. Psychological stress exacerbates hyperglycemia in most persons with DM by mobilizing glycogen resources in the liver and increasing glucose in the bloodstream. Cell membranes resistant to insulin prevent entry of glucose into the cells.

Management of DM comprises hypoglycemic medication (insulin and/or oral agents), which must be taken daily, regular monitoring of blood glucose, controlled diet, exercise, and stress management. The first steps rely on structured education about self-care; self-care behaviors remain the cornerstone of therapy. Changing dietary choices, increasing exercise, and learning to manage stress each require special skills and determination, which are facilitated by adaptive coping and social support from family and friends.

## THE DM MANAGEMENT TEAM

The team consists of the physician, the nurse/diabetes educator, and the patient functioning in a collaborative model of care. Health care providers monitor glycemic control by reviewing self-reported blood glucose data and regular assessment of glycohemoglobin by biologic assay. Frequent monitoring and keeping records of blood glucose levels provides information necessary to determine what works and what needs changing; thus, the management plan can be adjusted based on accurate data. Home glucose monitoring machines help to make blood testing easier and more accurate for tailoring one's daily plan for exercise, stress, and work or school demands. Most helpful is working closely with diabetes experts—physicians (e.g., endocrinologists, diabetologists), nurses (certified diabetic educators), nutritionists (registered dietitians), and exercise physiologists—in a program designed to meet the complex needs of people with diabetes. The counselor expert in stress management is fast becoming an integral part of the team to handle issues related to psychological stress or clinical syndromes common to diabetes patients, such as anxiety and depression. When medical or psychiatric comorbidity is present, the management plan needs to include recommendations for therapy of related illnesses.

## PSYCHOLOGICAL PROBLEMS IN PERSONS WITH DM

Affective disorders are common in persons with DM. Meta-analyses have confirmed the association between depression and higher blood glucose, poorer self-care, and more frequent complications of DM. Even depressed mood below the level of clinical depression is related to poorer glycemic control. Therapy of mood disorder with antidepressant medication and cognitive-behavioral therapy tends to normalize the neurochemical and behavioral factors driving the increase in blood glucose. In addition, minimizing depression improves positive health practices. Anxiety, whether free-floating or specific worry about diabetes, is frequently seen in persons with DM. Pharmacological, psychotherapeutic, or psychophysiological therapies for therapy of anxiety are available and effective.

## Self-Care

Both healthy eating and exercise have powerful effects on keeping the blood glucose within a healthy

range, thus preventing or delaying complications. Recent studies show that healthy diet and exercise patterns can help to keep one's blood sugar levels at near-normal ranges, and prevent or minimize short-term and long-term complications. People with diabetes often say that the hardest part of their regimen is eating a healthy diet and exercising. To avoid feeling helpless about having diabetes, the patient can function within an empowerment perspective by participating in decisions about managing the disease. Providers of care need to promote patients' desires to be involved in their own healthcare and to suggest avenues to empower patients for those with submissive traits. Better glycemic control is associated with more knowledge of self and personal needs and less helplessness. Realistic goals can be set and revised together to enhance the likelihood of success. Results of healthy eating and exercise are (a) having energy and a sense of well-being to enjoy life, (b) achieving near-normal blood glucose levels, (c) maintaining near-normal body weight, (d) preventing acute and chronic complications of diabetes, and (e) lowering blood pressure and plasma lipids in persons with DM who also have hypertension and hyperlipidemia.

### *Diet*

In the past, people with diabetes had rigid diet prescriptions and were told not to eat too many carbohydrates (breads, starches) and never to eat sugared foods such as sodas and desserts. Current guidelines are no longer for a "diabetic diet," but instead call for eating a healthy diet tailored to individual food preferences. The American Diabetes Association (ADA) recommends that people with diabetes follow the U.S. Dietary Guidelines for all Americans: eat a variety of foods; monitor portion sizes; eat foods high in fiber (fruits, vegetables, and whole grains); and consume fat, sodium, and sugar in moderation. People with diabetes need to know approximately how many calories or servings to eat each day from the three nutrient categories: carbohydrates, proteins, and fats. Specific recommendations are the responsibility of the physician and dietician, and usually are as follows: (a) protein: 10% to 20% of total calories (depending on kidney function), (b) fat: no more than 30% of total calories, and (c) carbohydrates: 50% to 60% of total calories. Fiber intake should be about 20 to 35 grams per day to enhance proper absorption of foods

from the intestinal tract and to promote normal bowel function. Other guidelines from the ADA include dividing meals into three per day about 5 to 6 hours apart, with between-meal snacks as needed; adjusting exercise and insulin (or other diabetic medication) to fit the meal pattern and to maintain proper blood sugar levels. Other recommendations are to minimize sugar intake by using FDA-approved artificial sweeteners and to use alcohol in moderation while accounting for the calories of alcoholic beverages. Avoidance of saturated fats (such as those in red meat, cheese, and butter) is also advised.

### *Meal Planning*

No specific meal pattern is right for all people with diabetes. Meal patterns can be as varied and flexible as needed to find a way that works for each person. Meal plans should be developed working with a certified diabetic educator to arrive at a design that fits the individual and can be followed. As with all plans, they can change when circumstances require, for example, if a child is growing rapidly or if an adult becomes more (or less) active. Factors influencing meal plans include cultural eating patterns, individual food preferences, activity level, medication schedules, and whether cooking at home or eating out. The goal is to eat a balanced diet at regular, predictable times that fit with one's lifestyle.

Scientific knowledge frequently changes in areas of nutrition, making it hard to know what is best. Although many fad diets are advertised to the public, people with diabetes should avoid fad diets that may be dangerous to their health. For example, the high protein diet sometimes promoted for weight loss is dangerous for diabetics, because eating too many protein foods (such as meat and eggs) can compromise kidney function. High carbohydrate diets (e.g., eating only fruits) may raise the blood sugar levels too much. Instead of fad diets, eating the right balance of protein, fats, and carbohydrates helps to maintain near-normal levels of sugar in the blood.

A current dietary debate is whether some kinds of carbohydrates are better than other types. Researchers are studying a factor called glycemic index, defined as the speed at which blood glucose levels rise after eating specific foods. Some carbohydrates (e.g., refined starches, flours, and sugars) seem to cause a more rapid increase in blood sugar than other carbohydrates

(whole grains and vegetables). Further research is needed to determine if this occurs in typical meals, and how blood sugar management is affected over the long run. Meanwhile, one may choose to eat more whole grains and vegetables and limit refined starches such as white rice, potatoes, and pasta while periodically testing one's blood sugar to observe the effects of various foods on the individual.

#### *Activity/Exercise*

As noted above, adequate exercise is one of the cornerstones for managing diabetes. Proper exercise benefits people with diabetes by enhancing the body's ability to use food and insulin, helping manage body weight, enhancing heart and blood vessel function, and promoting energy and positive mood. People with diabetes should remain active and have a prescribed exercise plan that fits their individual treatment program. The ADA guidelines are (a) exercise four to five times per week for 20 to 30 minutes, (b) monitor blood glucose levels to determine response to exercise, (c) eat a carbohydrate snack before exercising if blood glucose is less than 100 mg/dL, (d) carry candy or fruit juice if low blood sugar is a problem during exercise, (e) be sure to remain well hydrated by drinking water, and (f) always wear a medical identity tag in case emergency care is needed. As with all aspects of daily life, individuals should use trial and error in their exercise plan to see what works to enhance managing diabetes with enjoying life.

#### MIND-BODY THERAPIES

Models for stress management, relaxation, hypnosis, and biofeedback in DM are predicated on the relationship between psychological stress, the stress hormones, and carbohydrate metabolism. The association may be direct (via neurochemical and neuroendocrine pathways) or indirect, that is, mediated by behavior. The effects of the mind-body therapies depend on mental training (relaxation, adaptive coping, positive attitude) to decrease the mobilization of glucose from storage sites. The relationship between stress and blood glucose is variable among individuals, although most people react to acute or chronic stress with hyperglycemia rather than hypoglycemia. Evidence also exists that the mind-body therapies can facilitate lowering of blood pressure and blood glucose.

#### Support From Family and Friends

Behavior therapy is useful for family members of persons with DM, particularly adolescents with Type 1 DM. Less conflict within the family is associated with less reported personal stress for the diabetic person and lower blood glucose. Education of the best friends of adolescents increases support of the teen with DM and facilitates better self-care. When family members and the all-important peer group have a higher level of knowledge about diabetes, the teen copes more positively with the demands of the illness and is not embarrassed to take insulin or to make sensible food choices. The person with diabetes should also be viewed in the context of culture and ethnicity. People of different cultures react with considerable variability to the diagnosis of diabetes and management. Some believe that it is God's will or occurred simply by chance. The person's health beliefs and view of the care provider are relevant to adherence, particularly in intensive monitoring and medication regimens.

#### Cognitive-Behavioral Therapy

Both anxiety and mood disorders are treatable with cognitive-behavioral therapy (CBT). Countering negative cognitions and working through problems using a structured approach has been successful in decreasing psychological symptoms, decreasing the frequency of the stress response, and secondarily improving glycemic control. Often medical management is coupled with CBT for a more rapid response in individuals with more severe symptoms. Coping skills training assists persons with DM to overcome barriers to control and facilitates a sense of personal empowerment in self-care. Adaptive coping is associated with an improved sense of control further exemplified in decreases in glycohemoglobin. The positive effects achieved by learning are maintained over the long term.

#### Biofeedback-Assisted Relaxation

Biofeedback is a form of psychophysiological therapy in which an instrument monitors activity or physiological function, integrates the information, and displays it in an audio or visual format. Electromyograph and thermal biofeedback are used to provide

information about skeletal muscle tension and temperature of the hands and feet. Biofeedback is commonly combined with relaxation therapy in DM. Relaxation may include deep breathing, passive concentration, progressive relaxation, and imagery. About 8 to 12 sessions are necessary to learn the techniques. Home practice of relaxation is critical to skill building and generalization of the relaxation response.

Biofeedback has been studied in Type 1 and Type 2 DM with inconsistent results, despite improvements in anxiety in the participants. Positive effects on average blood glucose and percentage of fasting blood glucose values at target were observed in several studies of Type 1 DM. However, subclinical and clinical depressive symptoms appeared to impede the acquisition of the relaxation response or perhaps interfered with adherence to relaxation practice requirements or other self-care behaviors. Significant negative correlations were found between the magnitude of decrease in blood glucose and anxiety, negative mood, and number of daily hassles. A recent large study of stress management comprising progressive muscle relaxation and cognitive and behavioral skill training was carried out in Type 2 DM. At 1 year, significant decreases in glycosylated hemoglobin were observed. The group format used makes the use of relaxation-based therapy more practical and cost efficient. In addition to specific effects on blood glucose, thermal biofeedback has other applications relevant to DM. Acquisition of the foot-warming response with feedback is associated with improvements in peripheral circulation, faster healing of foot ulcers, and reduction in neuropathy pain in the feet.

### Complementary/Integrated Medicine Therapies

People with diabetes seek complementary therapies to decrease blood glucose, manage complications, gain a greater sense of control in their own disease management, or obtain a general improvement in quality of life. Types of therapies frequently sought by persons with DM include yoga, hypnosis, herbal products, massage, and meditation. For example, the regular practice of yoga exercises decreased the fasting and postprandial blood glucose values in Type 2 DM. As glycemic control improved, participants required fewer oral medications. However, controlled studies of these therapies in diabetes are sketchy, so blood glucose should be monitored closely by the management team. It should also be recalled that

interventions such as yoga are actually meant to be part of complete lifestyle programs, whose goals are broader than just decreasing blood glucose. Healthy nutrition, fitness, spiritual exercises, and better management of stress are incorporated in a total package that is meant to continue throughout the life span.

### SUMMARY

Long-term success in regulating blood glucose is a continuing challenge for people with diabetes. Empowerment is the term used to indicate high patient sense of self-efficacy in making good decisions in meal planning and activity. In that context, relapse into inactivity and overeating should be considered as a temporary relapse. The high blood glucose values may be due to psychological state, recent stress, or incipient clinical symptoms. In all cases, the patient's determination to get back on track should be affirmed. For the person with diabetes, the results of choosing well are both immediate and long term. In the short term, one has more energy and better mental function, feels less depressed, and has better vision when blood sugar levels are normal. In the long term, people with diabetes who eat well, stay active, and have learned to control the impact of psychological stress have fewer complications of diabetes. The treatment plan should not only consider blood glucose values and glycohemoglobin data but also cultural and personal health beliefs, mood, anxiety, coping, and social support.

## DIABETES: PSYCHOSOCIAL ASPECTS

---

This entry provides a summary of key findings from the behavioral science literature focusing on psychosocial aspects of diabetes mellitus (DM). The review considers specific issues such as psychosocial adjustment and psychiatric disorders, neurocognitive functioning, quality of life, stress and coping, family functioning, and psychosocial therapies. Children and adolescents are considered first, followed by a discussion of psychosocial issues in adults with diabetes.

### CHILDREN AND ADOLESCENTS

The incidence of Type 1 DM in young children has increased in recent years. In addition, the incidence of Type 2 DM has been increasingly recognized in older children and adolescents, often in association with obesity. Large numbers of children are currently affected by diabetes, and many more will be affected by diabetes in the future.

Diabetes imposes substantial demands on children and their families. As they are coping with normal developmental challenges, the additional burden of diabetes may be difficult for many children and families to deal with effectively. Especially challenging may be the demands of intensive management. Families play a significant role in the management of diabetes in children and are instrumental in the implementation of interventions. The quality of life of all family members may be affected by diabetes.

### Psychological Adjustment

Studies have shown that Type 1 DM is a risk factor for the development of psychiatric disorders in children and adolescents. For example, many children have adjustment problems soon after the diagnosis of diabetes. While the majority of these problems resolve within the first year, continued problems increase risk for poor adaptation to diabetes, including regimen adherence problems, poor metabolic control, and persistent psychosocial difficulties. Many mothers of newly diagnosed children are also at risk for adjustment problems of their own, with significant depressive symptoms observed in approximately one third of mothers; however, the majority of these subside within the first year after their child's diagnosis risk.

Research has also shown that risks for depression and eating disorders are higher in youths with diabetes and likely to be associated with poor metabolic control. A 10-year longitudinal study found nearly half of the study sample had a psychiatric diagnosis, the most frequent being depression. Another 10-year longitudinal study found lower self-esteem among young adults with diabetes. Poorer psychological adjustment during adolescence may persist into adulthood.

Studies also indicate that diabetic youth, particularly adolescent girls, are at increased risk for eating disorders. Both eating disorders and subclinically disordered eating attitudes and behaviors (e.g., repeated insulin omissions and severe dietary indiscretions) have been observed in adolescent girls with diabetes and are associated with worse metabolic control diabetes. Without intervention, disordered eating and insulin manipulation may worsen over time and increase the risk of health complications. At least 10% of adolescent girls with Type 1 DM meet diagnostic criteria for an eating disorder, a rate twice as common as in girls without diabetes. Without intervention, disordered eating and insulin manipulation may worsen over time and increase the risk of health complications.

### Neurocognitive Functioning

Studies indicate that children who develop diabetes prior to age 5 and/or who have frequent episodes of hypoglycemia are at risk for neurocognitive deficits, particularly in visual-spatial functioning. In addition, research has shown that children with diabetes miss more school than peers without diabetes, and that lower reading achievement was related to more school

absences. Learning problems are more likely in diabetic children, especially among boys.

Other research has found that children with a history of significant hypoglycemia have poorer attentional functioning and lower verbal intelligence. A longitudinal study with newly diagnosed children revealed declines in verbal intelligence and school grades, predicted in part by memory dysfunction. Another study showed that several years after diagnosis, children exhibited mild neuropsychological deficits, including reduced speed of information processing and decrements in conceptual reasoning and acquisition of new knowledge, which were predicted by both recurrent hypoglycemia and hyperglycemia, as well as early onset (prior to 5 years of age) of diabetes.

### Quality of Life

Relatively few studies have specifically examined quality of life in children and adolescents with diabetes, and those that are available have used a disease-specific measure. Research findings indicate that better diabetes quality of life in youths is associated with increased self-efficacy and less depression. Findings relating quality of life to glycemic control have been inconsistent. However, a recent study of over 2,000 adolescents found that better glycemic control was associated with lower impact, fewer worries, and greater satisfaction. In addition, girls reported more worries and less satisfaction than boys, and patients from ethnic minority groups had more impact and worries. More studies using generic measures of quality of life are needed.

### Stress and Coping

Researchers have also studied the role of stress and coping in relation to diabetes management. Findings indicate that children who have less life stress and who cope well with diabetes management are more likely to have fewer problems with regimen adherence and glycemic control. High levels of self-efficacy and low levels of learned helplessness have been associated with good glycemic control. Specific health beliefs related to the seriousness of diabetes, personal vulnerability to complications, costs of regimen adherence, and beliefs in the efficacy of treatment have also been associated with both regimen adherence and glycemic control.

### Demographic and Family Factors

Research has demonstrated that regimen adherence and metabolic control typically decline over time, and that the risk of metabolic control problems is higher among single-parent, lower-income, and African American youths. Family factors are reliably associated with regimen adherence and metabolic control: low levels of family conflict and stress, high levels of cohesion and organization, good communication skills, and appropriate involvement of both parents and children in diabetes management have been associated with higher levels of regimen adherence and better metabolic control. When parents allow adolescents to have self-care autonomy without sufficient cognitive and social maturity, they are likely to have more problems with diabetes management.

### Psychosocial Interventions

A number of controlled studies have examined the efficacy of psychosocial interventions for diabetic children and adolescents. Most of these have included the family as an integral part of treatment. Research findings indicate that family-based behavioral procedures such as goal setting, self-monitoring, positive reinforcement, behavioral contracts, supportive parental communications, and appropriately shared responsibility for diabetes management have improved regimen adherence and glycemic control. In addition, such interventions can improve the parent-adolescent relationship. Interventions with children and their families that promote problem-solving skills and increase parental support early in the disease course have improved long-term glycemic control of children. The efficacy of group interventions for diabetic youth has also been systematically evaluated. For example, research findings have shown that peer group support and problem solving have improved short-term glycemic control. In addition, stress management and coping skills training have reduced diabetes-related stress and improved social interaction and quality of life in adolescents.

### ADULTS

Because diabetes is such a psychologically and behaviorally demanding disease, psychosocial factors are relevant to nearly all aspects of its management. In studies with adults with diabetes, the psychosocial

impact of diabetes has been recognized as a stronger predictor of mortality than many clinical and physiological variables. Given the importance of psychosocial factors in diabetes management, the rapidly increasing number of adult patients with diabetes (mostly Type 2), and the growing and substantial public health burden of diabetes, the development and clinical implementation of effective psychosocial interventions are essential. Such interventions could help patients improve self-care behaviors and glycemic control, thus improving their quality of life and reducing their risk of health complications.

### Psychological Functioning

A substantial research literature has documented the prevalence and course of psychiatric disorders in adults with diabetes, particularly affective and anxiety disorders. Research findings indicate that depression is more common in patients with diabetes than in the general population, with at least 15% of patients having clinical depression. Depressed patients are likely to have worse glycemic control and more health complications, as well as decreased quality of life, and depression is likely to be persistent. A recent meta-analytic study demonstrated the association of depression with hyperglycemia and complications in both adult Type 1 and Type 2 DM. Furthermore, results from prospective studies indicate that depression doubles the risk of the incidence of Type 2 DM independent of its association with other risk factors. In patients with preexisting diabetes, depression is an independent risk factor for coronary heart disease and appears to accelerate its presentation. Research has also shown that anxiety disorders are also common in adults with diabetes and associated with poor glycemic control.

There is evidence that the adverse effects of depression and anxiety on diabetes can be lessened by psychiatric treatment. Randomized controlled intervention trials have shown that treatment with either cognitive-behavioral therapy or antidepressant medication can improve both mood and glycemic control. Psychopharmacologic interventions have also been shown to reduce anxiety and improve glycemic control.

Studies indicate that eating disorders such as bulimia are common in adults with diabetes, especially among young women with Type 1 DM. Research has also demonstrated that eating disorders are associated with poor glycemic control and increased risk for retinopathy.

### Psychosocial Factors and Stress

Research has also examined the effects of the social environment on diabetes management. For example, greater levels of social support, especially diabetes-related support from spouses and other family members, have been associated with better regimen adherence. Increased levels of environmental stress have been associated with lower regimen adherence and poor glycemic control; however, the effects of stress appear idiosyncratic and depend upon a number of factors, including the type of stressor and coping response and prestress metabolic factors. There is also evidence indicating that social support may buffer the negative effect of environmental stress on blood glucose.

Research findings suggest stress may be involved in the etiology of Type 2 DM. For example, studies with the ob/ob mouse (genetically obese mouse) have shown that environmental stress interacts with obesity to increase glucose intolerance. This hyperglycemic stress response can be lessened by antianxiety drugs and can be classically conditioned. Recent studies with humans provide support for the idea that stress may increase the risk for Type 2 DM.

### Neurocognitive Functioning

Neurocognitive deficits have been observed in adults with Type 1 DM. Patients with at least five episodes of severe hypoglycemia and those with peripheral neuropathy appear at greater risk. Poor glycemic control has been related to cognitive deficits in studies with older adults with Type 2 DM.

### Quality of Life

Studies have shown that diabetes-specific quality of life of adults is improved by increased physical activity and adequate social support. Improved quality of life has also been demonstrated after intensification of insulin regimens, an effect related to patients' greater perceived flexibility in physical activities and diet. Quality of life is adversely affected by the presence of health complications and comorbid psychiatric disorders, as well as physical complaints and worries about the future. In addition, research has shown that quality of life is lower when diabetes-specific health behaviors are perceived by patients as burdensome.

## Psychosocial Therapies

A number of controlled studies have evaluated the effects of psychosocial interventions for adults with diabetes. A recent meta-analytic review of diabetes self-management interventions showed significant improvements in glycemic control, as well as reductions in diabetes-related hospitalizations and health care costs, particularly when interventions incorporated individually tailored behavior change strategies. For example, interventions that increase patients' self-management skills and sense of empowerment have resulted in improvements in self-efficacy, self-care behaviors, glycemic control, patient satisfaction, and quality of life. These benefits have also been found in studies with older minority patients with Type 2 DM. Blood glucose awareness training with patients who have Type 1 DM has been shown to reduce the frequency of severe hypoglycemia episodes, diabetic ketoacidosis, and automobile accidents, as well as reduce the fear of hypoglycemia.

## SUMMARY

A significant amount of behavioral science research has demonstrated that psychosocial factors play an integral role in the management of diabetes in children, adolescents, and adults. In particular, patients with diabetes are at increased risk for psychiatric disorders, including depression and eating disorders, and these disorders are associated with glycemic control problems and health complications. Environmental stress and maladaptive coping and health beliefs are associated with problems with regimen adherence and glycemic control, while effective social support and adaptive coping are related to improved diabetes management behaviors and glycemic control. Research has shown the efficacy of a number of psychosocial therapies that can improve self-care behaviors, glycemic control, and psychosocial functioning and quality of life. More research is needed to develop psychosocial intervention programs for specific patient populations and to demonstrate the cost-effectiveness of these approaches.

## DIFFUSION OF INNOVATION

---

The diffusion of innovation model offers a schema for understanding how change takes place within a social system. The model is based on two underlying premises: (1) new ideas, products, and practices can alter the structure and function of a social system, and (2) communication is essential for the diffusion and subsequent acceptance or rejection of new ideas. The diffusion of innovation model describes how an idea, a product, or a process—labeled an innovation—spreads or diffuses through a defined social structure. One measures change by calculating how many people or groups of people adopt the innovation over time.

The diffusion of innovation model grew out of an interest in social transformation. Anthropologists and sociologists explored the consequences of the development, the spread, and the adoption or rejection of innovations that changed a social system. For example, anthropologists such as Robert H. Lowie

and Clark Wissler retrospectively studied the spread and modification of dance ceremonies among Native American groups, the introduction of the horse within and among indigenous population groups of North America, and the spread of corn cultivation from America to Europe. Early sociological studies in Europe and in the United States explored social and legal trends, the influence of a city on surrounding areas, the diffusion of governing practices, and the use and consequences of technology such as radio. Rural sociologists such as Herbert F. Lionberger and anthropologists such as Ward H. Goodenough focused on the spread of new ideas among farmers and the subsequent change in agricultural practices. Thousands of studies in myriad fields have added to diffusion literature. Everett M. Rogers charts this literature in a 1995 text, and earlier, Rogers and F. Floyd Shoemaker offered findings, primarily from agriculture and development studies, in the appendix of their 1971 text.

The diffusion of innovation model influenced the development of communication theories and social marketing models and continues to be widely applied in marketing, education, policy, health communication, and public health. Lessons learned from diffusion studies in rural sociology, education, folklore, communication, marketing, economics, and public health have helped contemporary scholars and practitioners transform the diffusion of innovation model from a descriptive model into a proscriptive one. Marketing experts and public health practitioners, for example, apply lessons from observational studies to purposively shape innovations and to plan programs of change. As a result, what had been a descriptive model is used as a theory to guide the design of products, programs, and communication strategies.

## KEY FACTORS IN THE DIFFUSION MODEL

The diffusion of innovation model focuses on change, offers a schema for understanding how it takes place, and measures it by calculating how many people adopt the new idea or practice. Scholars contributing to the descriptive diffusion model analyzed many features of the process and highlighted specific elements that impeded or facilitated the communication and adoption of new ideas. Research findings across many fields of study indicate that the diffusion of ideas among individuals within social groups depends on the features of the innovation, the channels

of communication, time factors, and the characteristics of the social system. Program planners and communication specialists, using the model to shape their work, may modify one or more of these elements to speed up the diffusion process and to engage groups that might ordinarily learn about the innovation much later in the process or not at all.

## The Innovation

An innovation may be a product, a practice, or an idea. It may be a recent invention or simply something new to members of a particular social group, as was the horse to the indigenous population of North America when the Spaniards first arrived. An innovation perceived as useful by members of a population may more easily spread than would an innovation seen as odd and of little relevance.

Descriptive studies indicate that the characteristics of an innovation clearly influence diffusion, adoption, and rejection. These characteristics include the dimensions of an item, the meaning it has for people, and whether or not people can easily talk about it, see it, and try it. Potential adopters consider the social and financial costs of trying out and/or adopting the idea or item and often weigh these costs against anticipated benefits. The ramifications of acceptance, including value as well as possible loss or danger, are important concerns.

Thus, the features of the innovation are critical considerations and will influence the diffusion process. For example, an innovation that fits with existing practices or beliefs, that is relatively simple, that has low investment costs, and with yields and benefits that can be easily observed by others will have advantage over one that clashes with predominate beliefs, is complex, costly, and subtle.

Many innovations, however, are adopted in part, put to new uses, or are modified by social groups or institutions. Such reinvention is part of the diffusion process. Consequently, innovations must be considered malleable. Those seeking to trace the diffusion process for a particular item may well need to differentiate between those item characteristics that are key and those that can be easily discarded without compromise. Public health nutrition program designers, for example, often seek to package or modify messages to achieve a better fit with a particular population's food preferences and needs but keep, as core, the central defining nutritional components.

## Communication Processes and Channels

Geography, social norms, and social structure shape communication, the key element in diffusion. These, in turn, determine differential access. Therefore, diffusion depends upon information exchange processes and on considerations such as who talks to whom, who is considered influential and trustworthy, and who has easy access to or is barred from various communication channels.

Communication channels include interpersonal as well as local and mass media. Interpersonal considerations often examined in diffusion studies include the characteristics of those people who introduce the innovation, of those who provide information or advice, and of those who influence the decision to try, adopt, or reject the new idea. Early diffusion studies indicate that initial innovators are often viewed as deviants by members of social and institutional groups and are accorded dubious status. Others, called opinion leaders, have access to outside channels of communication and are often in a position to learn about these innovations and observe the use put to them by those on the edge of their community. Opinion leaders, however, have high social status, and their adoption of an innovation is consequently viewed more seriously. Thus, opinion leaders tend to officially introduce the innovation to a large social group. Others, often professionals, show or bring the innovation to others as part of their role. They may more directly influence decisions of members of multiple social groups and are called change agents. They tend to be most powerful in this role when they are very like or are actual members of the groups faced with adoption decisions. Overall, the social and geographic proximity of various members of the population to opinion leaders and to agents of change will influence the flow of ideas and the adoption processes.

In a similar manner, researchers analyze the more distant and less personal media in terms of scope and reach and examine differential access to the local and mass media among various population groups. The mass media channels of national radio, newspapers, television, and the Internet may reach a select group in a population; however, the more local media such as postings, newsletters, and community radio may reach others who do not have easy access to the more costly or distant channels.

Modification in the various channels of communication can serve to facilitate the diffusion process. For example, Internet use spread more widely among less

affluent population groups once public access to computers and to the Internet were possible through cafes, libraries, and schools. In addition, findings from adult literacy surveys conducted in the early and mid-1990s within 22 industrialized nations brought attention to issues of literacy. These included the reading level of written materials, the vocabulary and format of spoken messages, and the functional literacy skills of members of the population. This work enabled program and communication designers to identify barriers that had not been attended to earlier and make modifications in written and oral messages designed for the public.

## Time

Analysts chart the diffusion process over time and consider the number of individuals, groups, or collectivities who adopt an innovation as the unit of analysis. Some innovations diffuse quickly through a population; others move slowly. Characteristics of the innovation, of the communication channels, and of the social system will influence the time it takes for an idea or process to take hold.

Analysts and program evaluators can track the diffusion process, over time, from the introduction of the innovation to adoption or rejection. Consequently, they can determine the direction of the flow of information, develop mathematical descriptions of variations in the process, and construct models.

The time element was also used by early contributors to the diffusion literature as a mechanism for dividing adopter groups into categories such as innovators, early adopters, early majority, late majority, and laggards. A deeper understanding of the social structure, however, helped many researchers and program designers recognize that “laggards” were often those who were distant, disadvantaged, or marginalized. Program and communication planners need to identify the characteristics of those who adopt an innovation early and those who come late to the process. Such information yields insight into needed modifications in the product, message, or communication processes. Thus, while time can be used to delineate groups, the social system factors must be used to understand them.

## SOCIAL SYSTEMS

Diffusion of innovation is always studied within a social system that is defined by geography, culture,

politics, affiliations, and/or institutions. The social and geographic boundaries of the structure within which an innovation is introduced will influence the flow of the diffusion process. Laws, rules, and norms influence patterns of interaction and govern communication. Structural arrangements within and between groups may limit or facilitate such patterns. Thus, systems influence both the flow of ideas and the behavior of members.

Characteristics of the social system also shape the types of decisions that can be made. Certain structures allow for optional individual decisions; others foster normative collective change; some impose change based on authority and power. Therefore, researchers and practitioners consider power and hierarchy, map differentiation and distribution of roles and status, examine networks of social relations, and seek to understand the values of the dominant as well as of the less powerful groups in a social system. For example, some groups in a society may hoard information about innovations for their own profit because they miscalculate others' interests or capabilities, or because they are unable to communicate across social divides. In addition, access to resources, including information, may differ between and among groups. These analyses enable program planners in public health, for example, to consider social determinants of health in the design of programs for healthful change. Consequently, innovations are often introduced to legislative bodies and institutions because changes in laws, in institutional patterns, and in physical as well as political and economic environments are often considered precursors to individual or community change.

## DISASTERS AND HEALTH

---

Research on cataclysmic events such as war, disasters, abuse, assault, and other traumatic or highly threatening events has increased over the past 50 years, as interest in extreme stress has increased as well. This work has overcome a number of methodological obstacles in studying these events and has applied eclectic theory and clever logistical solutions to what are often massive disruptions in people's daily lives. The study of disasters has developed very rapidly, and we have a much better understanding of how people react to them than we did even 20 years ago. This research highlights the extremely stressful nature of disasters and the conditions that convey most threat as well as the remarkable resiliency of humans and their ability to cope effectively with often overwhelming demands. We have also learned about some of the major effects of disasters on victims' mental and physical health.

### DISASTERS

Disasters generally refer to extremely disruptive, threatening, and potentially destructive events and their impact, as when a tornado outbreak strikes a community or an earthquake wrecks a part of a major city. In fact, disasters are best viewed as *disaster events*, powerful events that can cause substantial disorganization, death, disruption, and destruction to an area and the disaster itself, which reflects the degree to which disorganization and disruption materialized and destruction and bodily harm actually occurred. All hurricanes, for example, carry the potential to cause a disaster. The extent to which they cause such outcomes depends on their strength, speed, predictability, and where and when they strike. Striking at low tide or where few people live will minimize disaster impact, as will preparedness. *Disasters*, then, refer to situations surrounding disaster events characterized by considerable disruption of social and personal activities or networks, disorganization, and/or substantial injury, damage, and loss of life.

## Natural Disasters

Natural disasters are the most familiar of disasters, distinguished by their cause by natural events. Flooding, storms, earthquakes, volcanic eruptions, tornadoes, and avalanches are examples of natural disaster events, and as described above, these events may or may not cause disruption, disorganization, and death. Natural disasters are caused by natural forces and are not under human control. They are uncontrollable because they are a product of natural forces that we cannot stop. We can predict where and when they occur (in some cases), and this can help minimize disaster impact by allowing preparation or evacuation. However, natural disasters occur as a result of powerful, uncontrollable natural forces, and the extent to which the impact of these forces creates disasters depends on whether they cause significant distress, disorganization, and/or death or injury.

## Technological Disasters

Technological disasters are similar in many ways but are caused by events of human origin. This means that the disaster event is something that humans built, as in the case of building collapses, airplane crashes, nuclear power station accidents, or release of toxic agents, as in the cyanide disaster at Bhopal or the more gradually developing toxic hazards at Love Canal. These events are generally powerful and uncontrollable, like natural events, but represent a breakdown or loss of control over technology that normally is under human control. This *loss of control* over events assumed to be under our control may increase the duration of disorganization, disruption, or distress associated with technological disasters.

## MENTAL AND PHYSICAL HEALTH OUTCOMES

Disasters have a wide range of effects, including stress, stress-related mental health problems such as posttraumatic stress disorder (PTSD), and some profound psychopathology. Disaster-related stress can be associated with decrements in physical health such as increases in illness symptoms and progression of disease processes, not only during the initial aftermath of the disaster event but in the years following recovery. This relationship may be due, in part, to the effects of stress on important regulatory systems in the body, immune activity, cardiovascular reactivity, and other

systems that may affect health or contribute to disease. Poorer immune function could affect progression of already established diseases such as cancer or HIV disease, could affect inflammatory processes or immunization, and/or could affect vulnerability to viral infection. Stress-related cardiovascular changes include narrowing of arteries, increased adhesiveness of platelets, and increased demand on coronary arteries, and could contribute to this disease profile and/or precipitate cardiovascular events. For example, a middle-aged woman who has lost her home due to a tornado may experience more respiratory infections with more severe or more prolonged symptoms in the year following the tornado. At the same time, she may be exhibiting increases in cardiovascular reactivity. Continuation of distress and increases in physiological arousal may contribute to the development of hypertension 5 years after the tornado. Alternatively, in the case of disasters involving toxic hazards, stress may affect detoxification processes or other protective activity and ultimately influence the impact of toxic exposures.

Research has shown that disasters can have effects on physiological responses and bodily symptoms that can contribute to the etiology of disease or its progression. Heart rate, blood pressure, and stress hormones have been increased by disasters. And these changes may precipitate illnesses, particularly in cases where social support is atomized by the disaster, either due to death or dispersal of friends and family. Coping reserves may also be depleted by the massive coping required during the disaster event, intensifying these and other bodily responses. Health effects of disasters may increase when the period of intense stress is prolonged or when effects of the disasters last a long time.

Disaster victims may also worry about the possibility of negative health effects. They may believe that disaster event exposure will increase their risk not only for acute illnesses such as viral infections but also more chronic diseases such as cancer. These health concerns may be particularly prevalent after exposure to disasters involving the release of toxins such as chemicals or radiation fallout, but have also been documented in samples of victims exposed to natural disasters such as volcanic eruptions and floods. This worry and uncertainty over physical health outcomes may serve as an additional stressor and may potentiate disaster-related stress responding and could indirectly contribute to the manifestation of illness.

Stress due to disaster may also affect key health-related behaviors, like medication adherence, diet, and tobacco, alcohol, or illicit drug use that may have further effects on physical health. One can imagine scenarios such as one that would feature a young man experiencing stress due to a disaster event who copes by overconsumption of alcohol, which could lead him into high-risk sexual encounters, which could expose him to an infectious agent that would be only minimally defended by an immune response restrained by stress.

Most people affected by disasters recover fairly quickly, and within 1 year following disasters, the vast majority of people involved will have met the demands posed by the disaster and moved on with their lives. This does not appear to be the case with technological disasters, after which stress is less intense than during or right after natural disasters. However, stress following technological disasters appears to be more persistent and difficult to overcome. This could mean that technological disasters are more likely to have effects on physical health.

Some examples are illustrative. The nuclear accident at the Three Mile Island Nuclear Power Station (TMI) in 1979 was a watershed event for the nuclear power industry and spawned a good deal of research on the short- and long-term effects of nuclear accidents. The accident occurred when mechanical failure in the system that cooled the radioactive core and human error combined to expose the core and permit radioactivity to be released. Most of this radioactivity was captured within the reactor building, in water that spilled onto the building floor or as radioactive gas trapped in the reactor containment building. Once the immediate threat of meltdown or other serious mishap was controlled, the danger posed was reduced and area residents should have breathed easy. However, many did not, and a substantial minority of people living near the plant continued to experience stress for several years. Sympathetic hormones (epinephrine and norepinephrine) were elevated for at least 7 years, as was blood pressure and cortisol levels. Immune system activity was altered as well, and 5 years or more after the accident, some area residents showed smaller numbers of some immune cells and poorer control of latent viruses. Although none of these data provide a direct link to disease, chronic elevation of stress hormones and of blood pressure could contribute to hypertension or cardiovascular disease and possibly cause some of the observed immune

changes. The human cause of the TMI accident was coupled with the fact that the chief source of threat was radiation, which has effects that may take years to become evident. This meant that many area residents who feared that they had been exposed to radiation because of the TMI accident were worried about future harm yet to be realized. This kind of uncertainty is a prime contributor to chronic stress and to the kinds of effects observed.

Stress following the TMI accident also interfered with sleep, a key restorative process involved in maintenance of good health. Three years after the accident, TMI area residents reported more symptoms of physical discomfort, more awakenings during the night, and more time needed to fall back to sleep than did control participants living more than 75 miles from TMI. They also showed an unusual increase in stress hormones from when they were awake to when they were asleep. Control participants exhibited lower levels of stress hormones while asleep.

Other disasters have produced evidence of long-term effects that could contribute to ill health. Some involve sufficient exposures to cause death and disability directly. Following the nuclear accident at Chernobyl, in the Ukraine, some deaths occurred that were directly attributable to the accident. Similarly, during the cyanide release by the industrial plant in Bhopal, India, many victims died directly due to the release of the lethal gas. In addition to this, victims appear to have experienced significant distress and exhibited symptoms of stress similar to TMI-area residents.

The negative mental and physical health effects of disasters that are described above have been well documented in the literature. Fortunately, in most cases, these effects diminish rapidly over time as the victim deals effectively with the demands imposed by the disaster. However, for some victims, whose disaster event exposure was more intense or for whom their coping skills are not effective, stress symptoms can last for years to decades, and it is this group of victims who are especially at risk for long-term mental and physical health problems. In addition to these negative outcomes of disasters, a small literature is growing that documents positive mental health effects of disasters. Disaster victims report growing from their experiences in ways such as appreciating life and one's own vulnerabilities, putting more effort into relationships and becoming closer to support persons, and making changes in priorities. Perceiving a benefit

from exposure to a disaster may help to attenuate disaster stress and reduce concomitant physical health effects.

## DISCRIMINATION AND HEALTH

---

In race-conscious societies, race is a powerful predictor of access to societal rewards and a determinant of variations in health. Where social inequalities exist, discrimination is a key feature of intergroup relationships. Discrimination is important in serving to reinforce the symbolic boundaries that separate social groups from each other. Thus, racial categories capture an important part of the inequality and injustice that has historically and currently characterized racialized societies. There are multiple ways in which

discrimination maintains these social inequalities. Arguably, the most important mechanism in the United States context is an institutional one. Residential segregation is a primary cause of racial differences in socioeconomic status because it determines access to education and employment opportunities. In addition, segregation can have deleterious effects on health through the negative conditions it creates in residential environments. In addition, there is growing research interest in the ways in which the subjective experiences of discrimination may be an additional mechanism by which discrimination may affect health. This latter mechanism is the focus of this entry.

## THE PERSISTENCE OF DISCRIMINATION

There have been dramatic improvements in the racial climate in the United States in the last 50 years. On virtually every indicator of the endorsement of the principle of equality, there has been a large positive shift on the part of the White population, with the overwhelming majority of White Americans endorsing equality of opportunity for Blacks and other minorities in virtually every area of evaluation (Schuman, Steeh, Bobo, & Krysan, 1997). At the same time, other data suggest that racial attitudes are complex. The overwhelming support for the principles of equality coexist with substantial reluctance to support policies that would reduce racial inequalities (Schuman et al., 1997). In addition, data on stereotypes reveal the persistence of negative images of African Americans and other minorities. National data indicate that 56% of White persons believe that Blacks prefer to live off welfare, 51% believe that Blacks are prone to violence, 29% view Blacks as unintelligent, and 44% view them as lazy (Williams & Williams-Morris, 2000). Similarly, one in five or fewer Whites believe that Blacks are hardworking, not prone to violence, are intelligent, and prefer to be self-supporting. Moreover, Whites view all of the major ethnic minority populations more negatively than they view themselves, with African Americans viewed more negatively than all other groups and Hispanics viewed twice as negatively as Asians. Social psychological research indicates that when individuals hold a negative stereotype about a group, they will discriminate against an individual member of that group if they encounter one. Most important, this research shows that this process is both automatic and

unconscious (Hilton & Von Hippel, 1996). Thus, the persistence of negative racial stereotypes suggests that there will be widespread racial discrimination in the United States, with many perpetrators of racial bias being unaware of their discriminatory behavior.

Carefully executed scientific studies document the persistence of racial discrimination in multiple areas of society. Audit studies in employment and housing where Black and White applicants with identical qualifications apply for jobs or housing document continuing discrimination (Fix & Struyk, 1993). For example, audit studies in employment find discrimination that favors the White over the Black applicant 20% of the time. Similarly, a recent report from the Institute of Medicine documents widespread discrimination in the quality and intensity of medical treatment for a broad range of procedures in the United States (Smedley, Stith, & Nelson, 2003). Victims of discrimination are aware of at least some of these experiences and are able to describe them in both qualitative and quantitative research studies.

### **Discrimination: A Pathogenic Stressor?**

It has been argued that subjective experiences of discrimination are an important domain of stressful life experiences that traditional batteries used to assess stress have not included (Clark, Anderson, Clark, & Williams, 1999; Williams, Neighbors, & Jackson, 2003). Consistent with this view, equity theorists have also noted that perceptions of unfair treatment can lead to negative emotional reactions and psychosomatic symptoms. Several laboratory studies have assessed the physiological and affective reactions of African Americans to mental imagery and videotape vignettes of discriminatory behavior. These studies have found that exposure to such racist experiences leads to increased cardiovascular and psychological reactivity (Harrell, Hall, & Taliaferro, 2003). More generally, the experimental manipulation of unfair treatment in laboratory settings has a broad range of negative psychological consequences for individuals (Dion, 2001).

There are several reviews of the literature on the association between discrimination and health outcomes (Harrell et al., 2003; Krieger, 1999; Williams & Williams-Morris, 2000). This entry summarizes the findings of a recent review of population-based empirical studies that examined the association between perceptions of racial ethnic discrimination and health

and identified some 53 published studies (Williams et al., 2003). These studies have focused on both physical and mental health outcomes and we provide an overview of the research in each major area of investigation and some illustrative examples of the existing research.

### **DISCRIMINATION AND MENTAL HEALTH**

Mental health status is the most frequently assessed indicator of health in studies of discrimination. A broad range of mental health outcomes have been examined. These include measures of well-being, self-esteem, perceptions of control, psychological distress, anger, as well as specific psychiatric disorders such as major depression, generalized anxiety, and substance use. Moreover, some 80% of the 47 associations examined in the literature between measures of discrimination and an indicator of mental health found that higher levels of discrimination were associated with poorer mental health status. For example, a national study of over 3,000 American adults found that perceptions of acute and chronic discrimination were positively related to psychological distress, major depression, and generalized anxiety.

Most of the research studies in this area have been U.S.-based, and most studies have focused on the African American population. However, several studies have documented similar patterns of associations for other minority groups in the United States. For example, a study of over 3,000 Mexican Americans found that higher levels of perceived discrimination were positively associated with scores on the CESD depression scale. In a similar vein, a study of 1,747 Chinese American adults in Los Angeles who perceived discrimination based on race and language or accent was associated with psychological distress. A study of over 200 American Indian adolescents also found that perceived discrimination was associated with higher levels of substance use, psychological distress, and anger.

Equally impressive is the fact that studies in other countries are also finding inverse associations between discrimination and mental health. A study of 647 Southeast Asian refugees in Canada documented that perceptions of discrimination positively related to depressive symptoms. Studies in the Netherlands of both Iranian refugees, as well as Turks and Moroccans, find higher levels of discrimination associated with poorer mental health. Similar findings come from recent

studies in the United Kingdom. A national study in England and Wales found that perceptions of discrimination were positively associated with depressive symptoms and the annual prevalence of psychosis. A study in Ireland noted that experiences of discrimination were associated with higher levels of psychological symptoms among Black, Asian, and Arab adolescents and adults. A recent study of 1,146 immigrants in Finland also found an 18-item scale of discrimination to be positively related to levels of psychological distress.

## DISCRIMINATION AND PHYSICAL HEALTH

Multiple measures of physical health status have been examined (Williams et al., 2003). Six studies using a single-item global self-rated health measure have all found a positive association between discrimination and ill health. Nine of the 11 additional studies using other self-ratings of health or checklists of chronic illnesses documented that discrimination was related to poorer health status, at least under some conditions. For example, one recent study found perceived discrimination to be predictive of self-rated ill health and a composite measure of chronic health problems in a sample of 3,012 Mexicans in California. Similarly, in a probability sample of over 1,106 adults in Michigan, both chronic and acute discrimination were positively related to reports of ill health and chronic conditions for Blacks but not Whites.

There has been considerable interest in the association between discrimination and hypertension (Williams & Neighbors, 2001). Eleven studies have examined this association and the findings are mixed. Three studies have documented a clear positive association between discrimination and elevated blood pressure; in an additional five, this effect exists conditional on coping style, sex, socioeconomic status (SES), or race, and three studies find no association between discrimination and blood pressure. Illustrating the complexity of findings in this area, Krieger and Sidney (1996) found, in a sample of over 2,000 African Americans, that blood pressure levels were higher for women and working-class men who reported no discrimination *and* who reported discrimination in three or more social situations, compared to those with discrimination in one or two situations. Among professional men, discrimination was positively related to systolic and diastolic blood pressure.

Other health outcomes have also been examined. Perceptions of discrimination were unrelated to

self-reported heart disease in two studies, but a recent study found that perceptions of chronic discrimination were positively related to the onset of subclinical disease in the carotid artery for Black but not White women. Two studies have examined the association between perceived discrimination and low birth weight, and one has explored the association with adult mortality and the findings here have been mixed. Five studies have found a positive association between discrimination and cigarette use or alcohol consumption. Moreover, two studies have found that discrimination makes an incremental contribution above SES in explaining Black-White differences in self-reported health.

## RESEARCH ISSUES

In order to shed light on how perceptions of discrimination may be related to health, advances are needed in the conceptualization and measurement of discrimination and in the theoretical identification and the empirical verification of the plausible pathways by which this stressor can affect various health outcomes.

### Measuring Discrimination Comprehensively

Studies to date have not given sufficient attention to capturing exposure to discrimination comprehensively and to assessing the cumulative burden of such exposure over the life course (Krieger, 1999; Williams et al., 2003). Some studies have relied on single-item indicators of discrimination. Such approaches understate the actual level of discrimination. In most studies, participants' exposure to discrimination is measured at one point in time. In some studies, respondents were asked to provide a retrospective report about exposure to perceived discrimination over their life course, while other studies used a 30-day, 1-year, or 3-year time frame.

Research efforts are needed that would comprehensively characterize discrimination in multiple areas of social life. Like other stressful experiences, discrimination is multidimensional, and its assessment should provide coverage of all relevant domains. The most commonly assessed types of stressful experiences are life events, chronic stress, and daily hassles. Life events are discrete, observable stressors. Daily hassles refer to chronic irritations that are minor. Chronic stressors are ongoing problems that are often role related. They all have their analogues

among existing measures of discrimination. Major acute experiences of racial bias are the most commonly assessed type of discriminatory experience. The Everyday Discrimination Scale, developed by Williams and colleagues (1997), attempts to capture persistent and recurring, everyday, chronic minor experiences. However, that scale is generic, and it is important to capture measures of chronic discrimination in multiple domains, such as employment, educational, and public settings, as in the measure developed by McNeilly and colleagues (1996). In the general literature on stress, chronic stressors are stronger predictors of the onset and course of illness than are acute life events (Cohen, Kessler, & Underwood, 1995), but they are a challenge to measure. Measures of chronic exposure to discrimination are needed that directly assess the duration and frequency of exposure.

Traumas, nonevents, and macrostressors are other distinctive types of stress (Wheaton 1999) that point to promising areas of expansion for comprehensively assessing discrimination. Traumas are acute stressors, such as sexual assault that are severe, overwhelming in impact, and generally regarded as outside of the usual range of experience. Macrostressors are large-scale systems-related stressors such as economic recessions. Nonevents are desired and expected experiences that fail to occur. Most important, the various stressors have independent effects on health, such that an evaluation of the full impact of stress requires the inclusion of all relevant classes of stressors (Wheaton, 1999).

In addition to discrete acute and chronic experiences of discrimination, the structure and culture of racism can also create hostile environments in which the ever-present threat of discrimination can lead to heightened physiological arousal that can adversely affect health. Assessing the full impact of racism will require measures of vigilance that capture both the perceptions of danger in one's environment and the psychological and behavioral efforts to remain vigilant.

### Measuring Discrimination Accurately

There is concern in the literature that the salience of race can lead to some minority group members perceiving as race-related incidents that may not be, or even developing a mind-set in which they perceive incidents of racism that do not exist in reality. The available evidence suggests that these concerns may not be warranted (Williams & Neighbors, 2001). First,

respondents appear to interpret discrimination as intended by researchers, and self-reports of discrimination are consistent with objective experiences. Second, one national study has documented that baseline mental health status (psychological distress and major depression) is unrelated to subsequent reports of discrimination. Third, because reporting discrimination is likely to adversely impact self-esteem and perceptions of control, at least some minority group members are likely to minimize and deny experiences of discrimination. Thus, underreporting may be at least an equally serious threat to the validity of self-reports of discrimination as overreporting. Nevertheless, there is still the need for future research to adjust reports of discrimination for underlying psychological characteristics such as social desirability and neuroticism. Such adjustment strengthens the analytic design and increases the likelihood that observed associations between perceived discrimination and health outcomes might reflect a causal relationship.

At the same time, several strategies that have been used to improve the accuracy of the reporting of stressors should be applied to the study of discrimination as well. These include the use of cues to memory such as visual representations and reminders of personally salient events, wording the questions in ways so as to clearly define the domain of the experience being captured, and using a life-events calendar, which helps to date the onset and resolution of stressors (Williams et al., 2003).

Self-reports of bias also understate the full extent of exposure to discrimination. Given the nature of social interactions, subordinate group members will often lack full knowledge regarding any specific interpersonal transaction (Krieger, 1999). Secondly, and of greater challenge to measure, is the potential that some individuals cope with discrimination by minimizing or even denying its occurrence. Given the potential importance of the phenomenon of denial in research on discrimination and health (Krieger, 1999), future efforts to operationalize it in epidemiological research are a high priority.

Perceived discrimination relies on individual perception and emphasizes the attributions made by the individual. The subjective nature of discrimination and the ambiguity inherent in much interpersonal interaction often leads to uncertainty regarding the attribution of significant incidents of unfair treatment. The attempt to make sense of interracial interactions can stimulate physiological responses (Williams & Neighbors, 2001). The worry and rumination regarding

the causes of experiences of unfair treatment may be a part of the added burden that nondominant group members bear. Future research should assess the degree of ambiguity in the perception of discrimination and examine potential consequences for health.

One approach to reducing the salience of race in assessing discrimination is to first ask respondents if they have been treated “unfairly” in multiple domains of life (Williams, Yu, Jackson, & Andeson, 1997). After respondents have endorsed an experience of unfair treatment, they are asked to attribute a reason. Potential reasons include race and ethnicity, gender, age, religion, and sexual orientation. This approach enables respondents to report on all instances of unfair treatment, but allows the researcher to separate instances attributed to race from those linked to other reasons. Asking repeated questions about “racial discrimination” or experiences “because of your race” could produce demand characteristics in which the respondent believes that it is desirable to the interviewer to report such experiences. This could lead to overreports of discrimination. On the other hand, respondents may vary in their thresholds of what constitutes discrimination and fail to report as discriminatory incidents that were not perceived as very serious.

Information about the stressor of discrimination and its particular context is necessary for determining its impact. Key aspects of discriminatory experiences include the type or domain in which it occurs, the magnitude of the event, the temporal characteristics of the event, and the nature of the relationship between this stressor and other race-related and non-race-related stressors (Cohen et al., 1995). Beliefs about self, such as racial consciousness and identity, might affect the appraisal of discrimination, and other variables, such as social support and feelings of control, could enhance an individual’s capacity to cope and respond to discriminatory experiences.

The assessment of characteristics of discriminatory experiences should also include characteristics of the perpetrator. One study of African Americans found that experiences of discrimination were more strongly related to psychological distress when the perpetrator was also Black than when the perpetrator was White (Mays & Cochran, 1998).

### Understanding the Underlying Processes

One of the most critical research needs is for more careful attention to the specific mechanisms by which

perceptions of discrimination might adversely affect health. The literature on stress and health indicates that stressors can influence physical illness primarily through causing negative emotional states, such as anxiety and depression, which in turn can have direct effects on biological processes or patterns of behavior that affect disease risk (Cohen et al., 1995). It is thus plausible that one of the pathways by which discrimination can affect physical health outcomes may be indirect through psychological distress. That is, discrimination may lead to elevated psychological distress, which, in turn, may lead to chronic physiological arousal of the cardiovascular system. Research also needs to assess the extent to which reports of discrimination and the negative emotional states created by them might lead to health behaviors, such as impaired sleep patterns, decreased physical activity, increased substance use, and consumption of more food than usual, that may ultimately affect disease risk. As noted, some studies found that exposure to discrimination is associated with problem drinking and cigarette smoking. Thus, health-related behaviors should be included in any comprehensive assessment of coping responses to discrimination. Experiences of discrimination and the negative emotional states created by them may also lead to lower levels of compliance with medical recommendations (Cohen et al., 1995). This latter mechanism has not yet been explored in the literature. Researchers should also give attention to assessing the contribution of discrimination not only to the onset of disease but also to its severity and course.

At present, our understanding is limited regarding how exposure to discrimination leads to changes in particular biological responses and health behaviors. Research is needed that would identify the conditions under which particular types of exposure lead through specific processes to affect health. Such research should assess the conditions under which specific physiological systems, such as the cardiovascular, the neuroendocrine, and the immune system, are affected by particular types of exposure to discrimination. We are also largely unaware of the psychological or biological vulnerability factors for discrimination and the extent to which a given race-related stressor can produce varying responses in different individuals or groups. We are also not cognizant of the genetic and psychological factors that can make some organ systems vulnerable to the effects of discrimination on health. In the stress literature, for example, greater genetic vulnerability to depression is associated with

an increased impact of stressful life experiences on major depression (Kessler, 1997).

## CONCLUSION

A growing body of research indicates that discrimination is associated with poor health status, with the association being strongest for mental health. At present, we do not know the extent to which exposure to perceived discrimination leads to increased risk of disease, the conditions under which this might occur, or the mechanisms and processes that might be involved. It is also not clear whether there is a dose response relationship between discrimination and changes in health status. However, the literature offers needed concepts, models, measures, and methods for rigorous and sustained scientific evaluation of the association between perceived discrimination and a broad range of health outcomes.

## DIVORCE AND HEALTH

---

Marriage constitutes one of the most basic human relationships, forming the foundation for family life. Both men and women enjoy a range of benefits from

marriage, including better physical health, mental health, and financial well-being (see Waite & Gallagher, 2000, for a summary). The end of marriage through either death or divorce effectively stops the flow of these benefits to the former spouse(s). But divorce differs from widowhood in key ways. Marital separation and divorce differ primarily in their legal status, rather than in their consequences for the health of the individual, so both are included in the discussion here. Divorce marks the failure of the relationship. It tends to be accompanied by acrimony between spouses (Hopper, 2000) and increased risk of domestic violence (Mazur & Michalek, 1998), leads to often substantial declines in financial well-being, especially for women and dependent children (Petersen, 1996), and declines in social and emotional support (Mirowsky & Ross, 1989). All of these changes might affect physical or emotional health.

## EMOTIONAL HEALTH

Married men and married women show better emotional health than those who are not married, on average (Mirowsky & Ross, 1989). A number of recent studies have attempted to assess the mental health consequences of marriage and divorce and to separate out these from the selection of emotionally healthy individuals into marriage and distressed or unhealthy individuals. These studies followed individuals over time as some marry, some divorce, and some retain their previous marital status. Consistently, transitions into marriage improve mental health, on average, for both men and women, and transitions out of marriage decrease it (Horwitz, Raskin, White, & Howell-White, 1996; Marks & Lambert, 1998; Simon, 2002). It is important to note that although rates of mental illness are quite similar for men and women in the United States today, women show higher rates of affective and anxiety disorders, with symptoms of nonspecific anxiety, distress, and depression, whereas men have higher rates of antisocial personality and substance abuse dependence disorders, which manifest themselves in antisocial behavior and drug and alcohol problems (Kessler et al., 1994).

Robin W. Simon (2002) found that divorce increases symptoms of emotional distress among both women and men, but women show greater increases than men in depressive symptoms following divorce. Both men and women who divorce report a significant increase in alcohol abuse. Simon also found that men

and women who divorced reported more depression and more alcohol problems earlier than those who remained married, which she interprets as both a cause *and* a consequence of disruption.

## PHYSICAL HEALTH AND LONGEVITY

Catherine E. Ross and her colleagues (Ross, Mirowsky, & Goldsteen, 1990) summed up the evidence on the relationship between marital status and longevity: "Compared to married people, the non married . . . have higher rates of mortality than the married: about 50% higher among women and 250% higher among men." The unmarried face especially high mortality rates for causes of death that have a large behavioral component, such as suicide (Smith, Mercy, & Conn, 1988), accidents, lung cancer, and cirrhosis.

Lee A. Lillard and Linda J. Waite (1995) found that divorced men faced chances of dying that were much higher than otherwise similar married men and about the same as those faced by men who were widowed, separated, or never married. The picture was comparable for divorced women, who showed higher chances of dying than married women *or than divorced women*, although never married and separated women fared as poorly as the divorced. The relatively poor health behaviors of divorced and widowed men certainly contribute to their higher mortality (Umberson, 1992). Divorce also seems to contribute to poor health and increased mortality through its effect on physiological functioning (Kiecolt-Glaser et al., 1987). Divorced women also seem to suffer from the reductions in financial well-being that tend to follow from marital disruption (Hahn, 1993; Lillard & Waite, 1995; Petersen, 1996).

## Selection Into and Out of Marriage and Health

Cross-sectional differences in both emotional and physical health between the married and divorced are sizeable, but may result from the selection of the healthy into marriage and the unhealthy out. Many recent studies have addressed this selection by following individuals over time to assess the relationship between *changes* in marital status and *changes* in physical or mental health. These studies consistently find that selection into or out of marriage does not account for the better physical (Lillard & Panis, 1996) or psychological (Horwitz et al., 1996; Marks &

Lambert, 1998; Simon, 2002) health of married men or married women. Something about being married and something about being unmarried affects health.

## DOCTOR-PATIENT COMMUNICATION

---

The delivery of medical care depends upon effective communication in the doctor-patient relationship. When patients fail to understand what they have been told and do not ask questions or express their true concerns, the medical visit can be compromised. Thirty years of research provides important insights into the challenges of doctor-patient communication and the factors that promote or interfere with the therapeutic relationship.

In human social interaction, effective communication involves the unrestricted exchange of meaning between people to establish a common understanding. This exchange can take various forms: *words* (spoken or written) constitute verbal communication, and *signs* constitute nonverbal communication (gestures, facial expressions, gaze and eye contact, body postures and movements, vocal tone and quality, interaction distance, touch, and appearance). Doctors and patients express their own and read each other's signs constantly (and usually unconsciously) at the same time that they are communicating verbally. People tend to infer the meaning of others' nonverbal cues and draw conclusions, correctly or incorrectly, about others' attributes, personality, behavior, beliefs, and feelings. A doctor might observe a patient's facial expressions of pain and understand what the patient is experiencing. Or the doctor may control or suppress his or her own negative nonverbal messages (e.g., worry, distress) and purposefully express positive signs (e.g., caring, concern) in order to build trust in the therapeutic relationship. In the medical interaction, the sensitivity of doctor and patient to each other's verbal and nonverbal messages strongly affects the success of their communication.

The content of doctor-patient communication tends to fall into two broad categories. *Instrumental* communication is focused on achieving certain goals or tasks (e.g., diagnosis and treatment plan). Doctors inform and educate patients to follow treatment regimens (e.g., take medication) and to accept responsibility for their health behavior (e.g., exercise, quit smoking). Instrumental communication involves seeking and providing information in order to achieve behavioral goals in the medical visit.

The second broad category of communication content is *affective* communication, which focuses primarily on feelings, emotions, and experiences. This affective, or relational, dimension of communication is critical in the building of trust. Particularly when they are ill, patients may be acutely sensitive to their doctor's bedside manner—a common term encompassing a wealth of information about the doctor's sensitivity to and affective communication toward the patient. Patients also attend to doctors' affective responses, such as when they question their doctors' reasoning or conclusions, express dissatisfaction with a therapeutic process or result, explain their noncompliance with a prescribed regimen, negotiate for one they like better, or announce that they intend to get a second opinion.

#### WHAT CAN GO WRONG IN DOCTOR-PATIENT COMMUNICATION?

Doctor-patient communication that is both precise and emotionally supportive is not easy to achieve. Patients and doctors typically have a limited amount of time together and may speak different verbal (and even nonverbal) languages, have different ethnic backgrounds and cultural customs, and hold different views about the illness. When patients are anxious or depressed, they tend to have thought and memory impairments that hamper their accurate reporting of information to their doctors and hinder both their recollection of their doctors' directives and their motivation to comply with them. When doctors use medical terminology, patients tend to be confused but fail to ask questions. Studies show that immediately after their medical visit, patients forget at least a third to as much as half of what their doctors have told them.

Doctors also contribute to communication problems, sometimes not listening well and interrupting patients when they express their concerns. Often, there is little time for detailed and clear explanations.

Of course, affective communication, particularly in the nonverbal channels, can subtly co-occur with the tasks of instrumental and/or affective verbal communication. A doctor's supportive touch on the arm, for example, can be paired with measuring the patient's blood pressure, or an encouraging head nod can be paired with an inquiry into symptoms. Certain other affective messages can be detrimental to the relationship, such as a doctor's nonverbal expression of disinterest (e.g., looking at the chart instead of the patient) or hurry (e.g., checking the watch while standing near and oriented toward the door). Such communication can be very subtle, but it conveys powerful messages to a patient.

Research shows that communication is affected by context. For example, older patients are treated differently than younger patients. Doctors tend to give less attention to the problems and disease burdens of older patients, and doctors are less likely to suggest health promotion and disease prevention regimens when patients are older. Older patients often have another person present at their medical visit (e.g., a relative or caretaker), and the presence of this third person can be helpful but can also disrupt the doctor-patient relationship.

#### THE POSITIVE OUTCOMES OF THERAPEUTIC COMMUNICATION

Effective doctor-patient communication is a valuable goal for several reasons. Patients are most satisfied with doctors who provide clear explanations in terms that they can understand, and who listen to their concerns, answer their questions, and educate them about how best to care for themselves. Patients are most satisfied with relationships that involve partnership with rather than authoritarian control by the doctor, and with a doctor they feel they can trust. Satisfied patients are more likely to remain loyal to their doctor, recommend him or her to others, and refrain from "doctor-shopping" and from initiating a malpractice suit if the outcomes of care are less than expected.

When patients and their doctors communicate effectively, patients are better able to adhere to treatment recommendations. This is a very important goal, because as many as 40% of patients fail to follow their recommended treatment regimens, resulting in billions of wasted health care dollars. Patients are more likely to follow recommendations they fully understand. When patients' and doctors' expectations for

treatment are in synchrony, better health care choices are made and patients remain committed to their choices. When patients and doctors communicate effectively, they can work together to solve problems and overcome barriers to adherence. Good communication allows patients to ask questions of their doctors, express their opinions, ask about their options, and state their preferences. Greater patient participation leads to more informed decision making, greater patient satisfaction, better adherence, and ultimately improved health and quality of life. In the long run, health care costs are reduced.

### HOW CAN EFFECTIVE DOCTOR-PATIENT COMMUNICATION BE ACHIEVED?

Interpersonal communication is a two-way street. Improving doctor-patient communication requires the attention of both individuals in the context of medical care. Doctors can significantly improve their patients' health care outcomes by systematically educating them about the procedures or prescriptions that are being recommended to them, the reasons for these recommendations, the expected benefit to the patient and the likelihood of that benefit, what alternatives exist for treatment, the risks of treatment, and the costs on several dimensions such as money, time, and trouble. (This is a system called PREPARED.) In the recommendation of medication for insomnia, for example, the doctor would tell the patient the exact name of the drug and explain how it works, note the importance of managing the patient's insomnia immediately with medication and then transitioning to behavioral techniques to enhance sleep, the doctor's expectation for how the medication could be expected to help the problem, the alternatives that should also be explored (e.g., reducing caffeine, using relaxation techniques), the risks of the medication (e.g., habituation, dependency, reduced alertness), and the potential expense.

The provision of detailed information with a system such as PREPARED does more than simply educate the patient; it signals to the patient the doctor's interest in being a collaborative partner in the patient's health care, and it builds the therapeutic relationship. As doctor and patient openly discuss the patient's concerns, the patient's attitudes and beliefs emerge. Open discussion of the patient's fears can help the doctor to correct the patient's beliefs and improve adherence to recommendations.

On a practical level, patients can be helped to recall their medical histories during the visit, using verbal supports and prompts to aid memory. During the visit, information materials can be reviewed with and then given to patients, and reminder notes can be written regarding what was discussed, decided, and recommended. Reminder post cards about yearly diagnostic tests (e.g., Pap, mammogram, cholesterol screening) can be sent to patients to improve their adherence to long-term screening recommendations. By building trusting therapeutic relationships, doctors can learn about family and cultural pressures and expectations that affect patients' health behaviors (e.g., food choices, work pressures, family stress), and patient care can be improved significantly by doctors' personal and cultural awareness, sensitivity, openness to discussion, and emotional and practical support. A doctor's focus on open and reciprocal affective and instrumental communication can allow patients' expressions of concern regarding the barriers they face in their care (e.g., the cost in dollars or lost work time, and pressures on child care and other family responsibilities). Without open communication, a doctor may never know that a particular therapy was ineffective for a patient because it was not taken correctly, or that a patient's illness was not diagnosed in its early stages because the patient failed to have a recommended screening test. Open communication also allows for the recognition of patients' treatable emotional symptoms (e.g., anxiety, fear, depression, and hopelessness) and provides reassurance to patients in the context of competent management and referral.

Doctor-patient communication can also be improved with a simple action on the part of the doctor—*listening* to the patient's story. Researchers have recently focused considerable attention on the importance of understanding how a patient conceptualizes illness and suffering in the context of his or her life. Listening requires complete attention on the present interaction with the patient, as well as empathy, non-judgment of the patient, and genuine concern. Long-term management depends upon helping patients to understand the meaning of their illness, to adhere to complex and difficult treatments, and to experience the doctor as a caring and supportive individual.

There are many things that patients themselves can do to improve therapeutic communication with their doctors. When communicating information to their doctors, they can work to be accurate reporters of their own medical and family history by making sure that

they fully understand the questions they are asked by their doctors and by endeavoring to remember and report the answers correctly. They should detail all medications they are taking, with their doses and schedules (by bringing the medication prescription containers, or a written list of their contents, to the medical visit). Studies show that accurate reporting by the patient requires attention, active effort, focus, concentration, and management of distress such as anxiety. Patients should also be prepared to list their concerns and symptoms at the beginning of the medical interaction so that the doctor can create a "problem list" to be dealt with during the visit. The patient should also list any problems that are complicating his or her care, such as excessive stress, marital problems, or feelings of depression, to name a few. Doctors should not be expected to guess the patient's concerns, conditions, or preferences. Effective health care communication requires that a patient make known to the doctor his or her choices regarding outcomes of care and quality of life. In disease treatment, a patient might clarify for the doctor what matters most to him or her (e.g., cognitive clarity versus complete pain eradication, quality of life versus its length). The most productive and effective therapeutic relationships occur when patients alert their doctors if they anticipate having difficulties in adherence (e.g., if they doubt the value of a recommended treatment or are unwilling to accept the side effects of a medication or cannot make recommended lifestyle changes because of family or job constraints). The best outcomes occur when patients work with their doctors to find a treatment they can be committed to and ask for assistance (which can often be provided by ancillary health professionals such as nurses, dieticians, physical therapists, and psychologists).

In receiving and processing information from their doctors, patients can improve their health care outcomes by requesting clarification of words and concepts they do not understand. Studies show that better decisions are made when patients ask questions of their doctors and even politely challenge the logic of medical decisions made on their behalf. Using the procedure of PREPARED, patients can make better medical decisions when they ask about their procedures and prescriptions, the reasons for them, what can be expected from care, the probabilities that their expectations will be met, as well as the alternatives, risks, and expenses of treatment. Better medical decisions can occur in the context of active patient

involvement (rather than passivity) in communication with their doctors.

There are other strategies, as well, for improving communication in the medical therapeutic relationship. Some patients find it helpful to bring a third person to their medical visit (a friend or family member) who can assist them in communicating with the doctor. It is essential that this individual's role and expected involvement be defined and made clear to the doctor at the outset (e.g., "This is my daughter, and she is just going to listen to be sure I do not forget anything" or "This is my wife, and she is going to ask some questions that we have about my condition"). If there are potential language barriers, the patient should ask for (or bring) an interpreter. Finally, for doctor-patient communication to be effective, it is critical for patients to accept responsibility for their health behaviors, such as by following through with methods provided for them (e.g., stress reduction clinics, smoking cessation programs, dietary counseling) and by providing honest assessments of their adherence to treatment recommendations.

Medical training typically does not emphasize doctor-patient communication. A course or two during medical school may touch on doctor-patient interaction in the context of psychiatry or social medicine, but most early medical training emphasizes the physical and life sciences. During the later, clinical years of medical school as well as during internship and residency, training in patient care includes attention to communication. Throughout the United States, residency (postgraduate) training programs in primary care medicine adhere to recent guidelines for emphasis on and evaluation of humanistic communication skills. Communication is learned mostly from mentors, however. In the ideal medical training program, sensitive, caring mentors model instrumental and affective communication that fosters good patient outcomes. In such programs, training is based on the findings from considerable research showing that instrumental tasks in caring for patients are not separable from affective tasks, that verbal and nonverbal messages from doctors are all extremely important to patient outcomes, and that a patient's inner healing requires a supportive, caring, and partnered relationship with his or her doctor.

## CONCLUSION

Research demonstrates that effective doctor-patient communication is indispensable to patient satisfaction,

adherence, and the positive outcomes of medical treatment. Doctor-patient communication can be strongly affected by situational factors such as time limitations, in the context of medical care as well as by characteristics of doctors and patients. Successful patient care can be brought about through doctor sensitivity to the instrumental and affective components of communication, including attentive listening to patients' experiences of their illness, attention to their nonverbal messages of emotion, clarity in the communication of information to patients, and facilitation of their active involvement in their care. Effective communication can be enhanced when patients are active participants in their medical visits, providing accurate information about their medical histories, current treatments, and adherence, and stating their outcome preferences.

## DRUG ABUSE: BEHAVIORAL TREATMENT

Contemporary psychosocial treatments for drug abuse generally come from two theoretically different positions: the learning model and the disease model. The learning model, which is the focus of this entry, flows mainly from an academic research position. This model rests on scientific evidence that drugs act directly on brain reward systems, much in the same way that primary reinforcers such as food, water, and sex do, to increase the likelihood that drug-taking behavior will be repeated. The learning model also assumes that drug use and abuse are learned patterns of behavior that are influenced by the same general principles of learning as other behaviors. The treatment approaches that have derived from the learning model, called behavioral treatments, call for the development of new ways of behaving on the part of the substance abuser, as well as reorganization of the abuser's physical and social surroundings, to work against tendencies to return to drug use. No drug use or controlled use may be treatment goals, depending on the characteristics and goals of the abuser. Treatment is professionally delivered, typically by individuals with postgraduate academic degrees.

In contrast to the learning model, the disease model assumes that drug abusers are more likely, perhaps because of their genetic makeup, to seek out and use substances to excess and that drug-seeking behavior is outside the control of the user. Treatment calls for admitting powerlessness over drugs or alcohol, and the basic goal of treatment is always total abstinence from all mood-altering substances. Treatment can be obtained from professional counselors, who are often individuals in recovery from substance abuse themselves, and/or from participation in self-help programs like Alcoholics Anonymous (AA) or Narcotics Anonymous (NA), in which substance abusers voluntarily assist each other with recovery efforts.

Although the disease model is highly regarded by clinicians and probably the most common approach to psychosocial treatment of drug abuse in the United States, it has not been widely researched and therefore currently lacks strong scientific support. In contrast, the learning model and behavioral treatments of drug abuse have been relatively well researched and have broad scientific support for their effectiveness. Four

well-known behavioral treatments, each of which has been demonstrated to be effective in controlled studies, are described in more detail in this entry: behavioral counseling/skills training, contingency management, behavioral marital therapy, and multimodal treatments.

## BEHAVIORAL COUNSELING/SKILLS TRAINING

Behavioral counseling/skills training emphasizes rearranging the patient's surroundings and learning specific skills believed to be important for discontinuing harmful drug use and avoiding a return to drug use. Whether the treatment goal is abstinence or moderation of harmful use, patients learn how to identify triggers and consequences of their drug use. For example, if drug use or problematic use is more likely when patients are in a particular place (e.g., bars) or in the company of certain people (e.g., former high school buddies), they are counseled to rearrange their plans to avoid or reduce contact with those places or people. Sometimes the goal might be to change the places in which the patient socializes with a particular person (e.g., get together with a particular friend at a sporting event rather than a bar). Regarding consequences, the individual is counseled to make very clear the negative consequences of drug use and to identify healthy options to the positive consequences that they receive from drug use and intoxication.

Patients often receive coping skills training in areas believed to be important to discontinuing drug use and avoiding a return to drug use. To combat the common problem of social pressure to use drugs, for example, patients are instructed in a step-by-step style in drug-refusal skills through role playing and other exercises. When moderation is the goal with problem drinkers, individuals are taught to monitor their drinking, set drinking limits, and to use specific strategies to limit the amount consumed (e.g., do not drink alcoholic beverages to quench thirst, take small sips, alternate between alcoholic and nonalcoholic drinks) (see Hester & Miller, 1995, chap. 9). Other aspects of social skills training and problem solving are also commonly included in behavioral treatments for drug dependence (Hester & Miller, 1995, chap. 13).

With regard to teaching nondependent, problem drinkers to moderate their intake, a series of experimental studies reported over a 10-year period indicated that 20% to 70% of clinical samples can learn to drink moderately and that those effects can be

sustained for up to 2 years (see Hester & Miller, 1995, chap. 9).

A number of well-controlled treatment-outcome studies also support the effectiveness of skills training in the treatment of alcohol dependence (Hester & Miller, 1995, chaps. 2, 13). Most of these studies have examined the effectiveness of adding social skills training to other treatments, and focused on assertiveness and related social skills. In a seminal study on this topic, for example, 40 adults hospitalized for alcohol dependence were randomly assigned to either (a) an eight-session skills-training group focused on drinking-related problem solving or (b) a control group in which similar topics were discussed but no specific training was provided. During a 1-year follow-up period, the skills group compared to the control group reported an average of fourfold fewer drinks consumed, sixfold fewer days drunk (11 versus 64 days during the 12-month follow-up), and a ninefold reduction in duration of drinking episodes (average of 5 days versus 44 days) (Chaney, O'Leary, & Marlatt, 1978).

The bulk of the evidence supporting the effectiveness of social skills training and other coping skills training has been obtained with alcoholics and problem drinkers, but more limited evidence is also available supporting the effectiveness of this approach with individuals who abuse or are dependent on illegal drugs like cocaine. In addition, numerous reviews and meta-analyses support the effectiveness of this approach for quitting cigarette smoking. Typically, patients are instructed to set a definite quit date, identify and avoid high-risk situations, develop strategies for dealing with urges to smoke, and ask for support in quitting from family and friends. The proportion of patients who successfully quit smoking at 6- or 12-month follow-ups generally increases as the intensity of the treatment increases, with 20% abstinence rates being common and 40% being reported in some early studies with intensive behavioral treatments. Combining behavioral therapy with pharmacological treatments (e.g., nicotine gum or patch) generally increases quit rates above either treatment alone.

## CONTINGENCY MANAGEMENT

Contingency management (CM) is a treatment approach that encourages behavior change by providing positive reinforcement dependent on, or contingent on, meeting treatment goals and withholding

reinforcement or providing punishing consequences when undesirable behavior occurs. While punishment can be effective in some circumstances, positive reinforcement is preferred. CM has been used effectively in the treatment of various forms of drug dependence, including amphetamine, alcohol, cocaine, marijuana, nicotine, and opiate abuse. While punishment can increase drug abstinence, it also increases treatment dropout. Positive reinforcement, on the other hand, reduces both drug use and treatment dropout.

Contingency management involves an agreement or contract that carefully lays out the desired behavior change, how progress in making the behavior change will be monitored, the consequences that will follow success or failure in making the behavior change, and the duration of the contract. Practical details on the development and use of CM interventions can be found in several sources, including Budney and Higgins (1998) and Higgins and Silverman (1999).

The most common use of CM with drug-dependent individuals is to reinforce refraining, or abstaining, from drug use. Numerous studies have shown that providing incentives contingent on objective evidence of abstinence from recent drug use (e.g., negative urine test results) increases future abstinence (see Higgins & Silverman, 1999). Although compelling evidence regarding the effectiveness of CM has been available since the 1970s, interest in this treatment approach was increased substantially by successes achieved with CM in the treatment of cocaine dependence. In a seminal study on that topic, 38 cocaine-dependent adults were randomly assigned to 24 weeks of behavior therapy, including CM, or to drug abuse counseling (Higgins & Silverman, 1999, chap. 2). In the CM condition, vouchers that could be used to purchase retail items such as gym memberships, fishing licenses, and gift certificates to local restaurants were earned by submitting urine specimens that tested negative for cocaine. More than 50% of patients in the CM condition remained in treatment for the recommended 24 weeks and achieved several months of continuous cocaine abstinence, while only 11% of patients in the comparison condition did so. Subsequent studies of CM in the treatment of cocaine dependence repeated those findings and also demonstrated continuing benefits during the year after treatment ended (Higgins, Wong, Badger, Haug Ogden, & Dantona, 2000). These positive results with CM were particularly encouraging because so few other treatment approaches have been shown to be effective with cocaine dependence.

Most typically, but not always, CM is used as one part of a more comprehensive treatment plan. Indeed, CM can be used to improve willingness to follow through with other parts of a treatment plan. For example, CM has been used to improve the likelihood of taking medications among individuals receiving disulfiram (Antabuse) therapy and tuberculosis-exposed drug abusers (Higgins & Silverman, 1999, chaps. 1, 16, respectively). CM can also improve participation in therapy-related activities, such as patients earning vouchers by completing therapy-related activities. The activities might include attending a job interview if the goal was gaining employment, or attending a self-help meeting if the goal was to increase contact with people who support sobriety. Vouchers can be provided when patients submit proof that they have completed a designated therapeutic activity.

CM is also proving to be capable of improving the success of treatment with important special populations of drug abusers. Improving the likelihood of taking medication among those with infectious diseases was noted above. Another special population is the seriously mentally ill who are also drug dependent. CM may be effective in reducing cigarette smoking and cocaine use among individuals with schizophrenia (Higgins & Silverman, 1999, chaps. 2, 5, respectively). CM is an essential component of a multielement treatment that is effective in the treatment of homeless crack and other drug abusers (Higgins & Silverman, 1999, chap. 4). Another special group for whom effective treatments are sorely needed is drug-dependent pregnant women. A voucher-based CM treatment has been demonstrated to significantly increase abstinence from cocaine and heroin use while at the same time increasing work-related skills among pregnant women who were both drug-dependent and chronically unemployed (Silverman et al., 2002). In another effective CM intervention with pregnant women, vouchers delivered contingent on abstinence from cigarette smoking increased quit rates during pregnancy and after delivery (Donatelle, Prows, Champeau, & Hudson, 2000).

## BEHAVIORAL MARITAL THERAPY

Evidence from studies with alcohol-dependent individuals and with individuals dependent on illegal drugs indicates that involving spouses who are not themselves drug abusers in treatment and providing them with behavioral marital therapy can improve the

quality of the relationship and decrease drug use. The evidence is stronger regarding improvements in marital satisfaction than reductions in drug use, but both have been documented in controlled studies. The rationale for involving spouses in treatment is that they can learn skills that may encourage abstinence or moderation; they can learn to avoid engaging in behavior that may start or encourage drug use; and spouses are an important potential source of alternative reinforcement when drug use stops. Two aspects of behavioral marital therapy seem particularly important. First, couples receive training in positive communication skills, such as how to negotiate for changes in each other's behavior that will improve the quality of the relationship. Second, when treatment involves disulfiram therapy for alcohol dependence, spouses are taught how to effectively monitor the taking of the medication.

Results from studies that included behavioral marital therapy in the treatment of problem drinking provide reason for cautious optimism, including three recent well-controlled studies by O'Farrell et al. (Hester & Miller, 1995, chap. 12). One study that included a 2-year follow-up involved 36 couples, in which the husbands had recently begun individual alcoholism treatment and received a prescription for disulfiram. Couples were randomly assigned to (a) a no-marital therapy group, (b) a behavioral marital therapy group, or (c) an interactional couples group. Couples in the behavioral marital therapy group signed a contract regarding the taking of disulfiram, and they received counseling to increase positive family activities and improve communication. Couples in the interactional group primarily shared feelings about their relationship during therapy sessions. Behavioral marital therapy produced better outcomes on marital adjustment ratings than the other conditions, but there were no significant differences in abstinence among the three groups during treatment or follow-up.

A more recent study by this same group suggests that adding sessions at the end of behavioral marital therapy that emphasize relapse prevention can improve outcomes in this treatment approach (Hester & Miller, 1995, chap. 12). Relapse prevention teaches patients skills to recognize high-risk situations for resuming drug use, to use other coping strategies when they find themselves in risky situations, and to apply strategies to prevent full-blown relapse should drug use occur. Fifty-nine couples, defined by the inclusion of an alcoholic husband, were randomly assigned to receive or not receive 15 relapse prevention

sessions upon completion of 5 months of weekly behavioral marital therapy that included a contract for disulfiram compliance. Abstinence improved significantly from levels prior to treatment in both groups, but couples who received the relapse prevention sessions reported significantly greater abstinence and greater use of the disulfiram contract during follow-up than those who did not receive the extra sessions. Improvements in marital satisfaction during follow-up as compared to before treatment also tended to favor the group that received extra sessions.

## MULTIMODAL TREATMENTS

Treatment packages are often put into place that use most of the individual behavioral treatments noted above as parts of a more comprehensive treatment effort, usually for severely dependent individuals. The Community Reinforcement Approach (CRA) is perhaps the best example of a multimodal-behavioral treatment. CRA includes various forms of coping skills and problem-solving training, vocational counseling, marital therapy, social/recreational counseling, and socially monitored disulfiram therapy (see Meyers & Miller, 2001).

In the seminal study examining the efficacy of the CRA treatment for alcohol dependence, 16 males admitted to a state hospital for alcoholism were divided into matched pairs and randomly assigned to receive CRA plus standard hospital care or standard care alone (Meyers & Miller, 2001, chap. 2). Following discharge from the hospital, CRA patients received a tapered schedule of counseling sessions across several months. During a 6-month follow-up period, patients who received CRA reported approximately sixfold to fourteenfold less time drinking, unemployed, away from their families, or institutionalized, compared to control patients. Several of the CRA elements noted above were added in subsequent studies conducted by this same group of investigators as the treatment moved from being an addition to inpatient treatment to a stand-alone, complete treatment that could be delivered in outpatient settings. Findings from these later studies were at least as impressive as in the seminal study (see Meyers & Miller, 2001). CRA has been effectively extended to the treatment of cocaine and opiate dependence (Higgins & Silverman, 1999, chaps. 2, 23, respectively). A contingency management element was added in the extension of CRA to the treatment of

cocaine dependence discussed earlier (Budney & Higgins, 1998).

Another multimodal program related to CRA is Community Reinforcement and Family Training (CRAFT). CRAFT was based on the idea that since family members can make important contributions in other areas of treatment, they can also be influential in helping to get reluctant drug-dependent family members into treatment. Some of CRAFT's basic components include discussing personal safety issues, identifying the situations in which drug abuse occurs, teaching family members how to use positive reinforcement for both the user and themselves, and emphasizing lifestyle changes for the family member.

In a seminal study examining the efficacy of CRAFT procedures for engaging problem drinkers into treatment (Meyers & Miller, 2001, chap. 8), 130 family members were randomly assigned to (a) Al-Anon therapy, which encourages involvement in the 12-step program and to get resistant drinkers to enter formal treatment, (b) a Johnson Institute intervention, which prepared the family member for a confrontational family meeting that led to formal treatment, or (c) the CRAFT approach. The CRAFT approach was significantly more effective in getting reluctant problem drinkers into treatment (64%) as compared with the more commonly used Al-Anon (13%) and Johnson Institute (30%) interventions. A modified CRAFT approach designed to engage illegal drug abusers into treatment has also been preliminarily tested, with promising results (Meyers & Miller, 2001, chap. 8).

Significant progress has been made in the development of effective behavioral treatments for drug abuse. Learning-based treatments emphasizing step-by-step reinforcement of abstinence, positive lifestyle changes, skills training, and participation of significant others in treatment have been shown to be effective treatments, but there is room for improvement with all of these approaches. Careful assessment of the necessary parts, length, and intensity of treatment, as well as more effective transfer into standard clinical practice remain important challenges for behavioral treatments of drug abuse.

## DRUG ABUSE: PREVENTION

---

Drug abuse, including tobacco and alcohol abuse, is a major health and social problem in the United States, contributing significantly to both adult and youth morbidity and mortality. The field of drug abuse prevention aims to reduce these morbidities, mortalities, and attendant costs by two means: preventing onset of drug use among youth, and preventing progression to heavy use and abuse among those youth who have already started using drugs. The purpose of this entry is to review effective drug abuse prevention

efforts, issues in prevention, and future directions for research and practice.

## WHAT IS MEANT BY PREVENTION?

Prevention is defined as any program or strategy that has as its goal either delay of onset, delay of progression from lower to higher use prevalence (frequency) or consumption (amount), or decrease in prevalence and consumption of tobacco, alcohol, and other drugs. The majority of prevention strategies are school-based programs for youth. While these programs range from childhood to late adolescence, most start in middle school. This period, corresponding to early adolescence, is marked by an increase in experimentation with tobacco, alcohol, and marijuana. Prevention focuses heavily on deterring use of these drugs, which are referred to as gateway drugs for their temporal, if not causal, relationship to use of other substances later in adolescence and adulthood.

### Types of Prevention

Preventive efforts can be generally cross-categorized by three types. These include approach to drug abuse control (demand vs. supply reduction), level of prevention (universal, selective, indicated), and focus (reducing risk factors vs. promoting protective factors).

Most prevention programs approach drug abuse control through *demand* reduction—that is, changing youth by changing favorable youth attitudes, perceptions, and behaviors related to drug use. Demand reduction programs tend to emphasize both personal and social influences on drug use, and include skills in decision making, resistance, assertiveness, and normative change, among others. Prevention efforts aimed at *supply* reduction efforts, on the other hand, are focused primarily on changing youth supply, availability, or access to drugs. Supply reduction efforts include formal policies and ordinances on restricting youth access to drugs, enforcement, and/or taxation; voluntary restrictions such as vendor agreements not to sell tobacco and alcohol products to youth; and interdiction at borders and points-of-purchase.

Level of prevention refers to the target population. *Primary*, or *universal*, prevention targets whole populations of youth and typically is accomplished through education by teachers or peers in school settings. *Selective* prevention programs are for youth who

exhibit early problem behaviors that are associated with later drug use, including conduct problems, school achievement problems, or family problems of drug use. Selective programs include student assistance programs, parent-child communication and support programs, and tutoring programs. *Indicated* prevention programs focus on youth who are considered at high risk for drug use and already have one or more problem behaviors associated with later use, including truancy, school achievement problems, stealing, gang involvement, and conduct disorder. Prevention at this level is considered early intervention, and includes in-school counseling, outpatient counseling, and court-mandated programs for youth drug offenders.

Focus of prevention refers to the factors that predispose youth to either use drugs (*risk factors*) or not use drugs (*protective factors*). The majority of prevention efforts focus on counteracting risk factors for drug use and teach skills and strategies to resist drug use and avoid drug use environments. Risk factors for drug use and other problem behaviors include school failure, peer pressure, and lack of positive parent-child communication and support. Fewer programs focus on promoting protective factors against drug use, including social bonding, academic competence, support-seeking and communications skills, and general life skills such as decision making. Selecting a program that focuses on risk or protective factors depends largely on the age and level of drug involvement of youth at the point of intervention. For example, young children in elementary school may benefit more from a program that focuses on building protective factors of age-appropriate, prosocial bonding to peers and adults than from a program that teaches them how to refuse a drug use offer, since, for most children, drugs are not yet available. Alternatively, early and mid-adolescents may benefit more from training in skills to resist and avoid drug use offers and opportunities, since the frequency of these opportunities for drug use and practice of drug use resistance skills is higher in these age groups.

### Effective Prevention

Programs that have demonstrated significant delays or reductions in youth drug use are referred to as science- or evidence-based. Effective prevention programs share at least three common features: a basis in *theories of behavior change*, an emphasis on

*counteracting risk factors and promoting protective factors that mediate drug use, and use of strategies that enhance quality of program implementation and impact.* The remainder of this entry concentrates on effective prevention programs and strategies.

## BASIS IN THEORIES OF BEHAVIOR CHANGE

Basing prevention programs on sound theories of behavior change enables researchers to determine whether a program, if effective, changed behavior according to the mechanisms proposed by the (i.e., program mediators) theory or, if ineffective, failed to change behavior because the mechanisms themselves were not implemented or did not change.

Several theories help to explain how counteracting risk factors and promoting protective factors should work to change drug use behavior. For example, *problem behavior theory* posits that adolescents experience transition periods that make them feel vulnerable to peer pressure. Teaching skills such as decision making and resistance is an alternative way to build confidence.

*Expectancy theory* posits that a prevention program that promotes negative rather than positive norms for drug use will help curb drug use experimentation. *Social learning theory* posits that drug use will be prevented to the extent to which youth can be taught to emulate and bond with nondrug-using models for behavior, and practice resistance skills. *Social bonding*, or *social development theory*, suggests that activities to promote bonding to school and home will protect youth against drug use. Finally, *transactional theories* posit that three levels of risk and protection interact to either influence or prevent drug use: intrapersonal, social, and environmental. Prevention programs based on these transactional theories typically employ multiple components that are designed to have long-term synergistic effects.

### Emphasis on Risk and Protective Mediators of Drug Use

Prevention program mediators refer to those variables that are the immediate targets of a prevention program, such as resistance skills, are demonstrated to change as an immediate result of a program, and which in turn can be shown to prevent or decrease drug use behavior. Program mediators usually include skills or strategies to counteract risk and promote

protection. Risk and protective factors have been identified at three levels: the person (intrapersonal cognitions, affect, behavior), the social situation (interpersonal or group norms, attitudes, and behavior), and the environment (organizational, systems, community, or larger influences).

At the *intrapersonal level*, risk factors for drug use include prior use, positive beliefs about use, positive appraisal of the drug use experience, and lower perceived risk or consequences of use contributing to drug use. Counteracting these intrapersonal risk factors in combination and in their social context appears to be critical for achieving change in drug use behavior. Effective programs that counteract risk at this level combine personal beliefs about drug use risk, perceived personal consequences, and decision making specific to avoiding drug use. Programs that promote protective factors may combine personal choice of nondrug use activities, valuing of school achievement, and involvement in nondrug use activities. While most risk reduction and protective programs are universal, a few operate as selective or indicated prevention programs, such as prevention programs in continuation high schools for low-achieving youth and after-school programs for truant youth. Effects of intrapersonal level prevention programs have been shown on changes in program mediators and on school achievement for periods of 1 to 3 years.

At the *social level*, risk factors include exposure to drug use models, access and attachment to users, and positive perceived social norms for use. These prevention programs focus on counteracting social situational risk factors that typically include training in avoidance, peer pressure resistance, and/or assertiveness skills; weighing positive and negative consequences of drug use; and correcting perceived social norms for use. Social-level programs implemented during the elementary school years may focus on bonding with nonusing peers, family, and school. Most social influence programs are considered universal prevention programs because they include whole populations of school-attending youth. Selective or indicated prevention programs have typically focused on social support-seeking and selection of nonuse alternatives along with skills training. With a few exceptions, social influences programs have been effective in delaying and reducing adolescent drug use, for periods of 5 years or more, when compared with either control or standard health education conditions.

*Environmental*-level risk factors include exposure to and positive beliefs about media portrayals of drug use, exposure to drug use environment, access to drugs, low exposure to prevention programs and resources, and positive perceived environmental norms for drug use. Prevention programs that counteract these risk factors may include organizing and empowering community leaders to change drug use, enforce policy, and institutionalize prevention programs and resources. Environmental-level protective factors include positive media coverage of prevention and nonuse messages, financial resources for prevention, and community availability of organized structures, such as coalitions, to promote prevention programs. Programs that address environmental influences have consisted of either mass media programs or campaigns, policy enforcement or policy change intervention, community coalitions or partnerships organized for drug abuse prevention, or a combination. In general, mass media programs have produced small effects on changing attitudes toward drug use and beliefs about consequences and intentions to use drugs in the future. Restricted access policies that involve youth in enforcement, for example, through activism or sting operations, have an effect on decreasing tobacco sales and purchases by youth and may decrease alcohol consumption. Community coalitions tend to show a trend toward decreasing adolescent drug use, but effects are small.

All of these levels of factors interact to affect youth drug use. Comprehensive community-based programs attempt to integrate these factors by including multiple components in combination, for example, a school program with parent, mass media, and/or community organization training. Although it is not clear whether effects are additive or synergistic, the more comprehensive programs, overall, have shown large reductions in use prevalence by youth compared to control conditions (20% to over 60%) that are sustainable for 8 years or more.

### Strategies to Enhance Quality of Program Implementation and Impact

Several factors have been shown to enhance program implementation and impact on youth. The first is the use of standardized training or teaching materials and procedures for program implementers, who may be teachers, peers, counselors, parents, or service agency staff. A typical training session consists of at

least a day of training that follows the same process outlined in social learning theory to train youth: an overview of general principles, modeling, role playing, group discussion with feedback, and extended practice through homework assignments, or initiation of program implementation with observation. The second is the use of social learning theory methods of implementation with youth: Trainer-youth interaction is enhanced, often with the assistance of peer leaders. The third is the use of periodic booster programming. Finally is the set of techniques, settings, or individuals that can extend prevention beyond the program setting, including interactive homework with parents, and agreement to practice prevention skills outside the program setting.

### Diffusion of Effective Programs

Diffusion includes factors that promote *adoption*, quality of *implementation*, and *dissemination*, or the widespread use of a prevention program.

Factors that promote adoption of effective prevention programs include support of a local “champion” (a prominent, positive role model or organization), early positive communication about the program, pre-training of prevention leaders in knowledge about the program, and available resources.

Quality of implementation includes adherence to program materials and procedures as designed, delivery of the full amount of contact hours of programming, and flexibility for “reinvention” (i.e., some tailoring of the program to the specific needs of youth without sacrificing adherence). In addition to the factors noted in the previous section, quality of implementation increases with the availability of trained personnel, and efficient channels, structures, and processes to implement and monitor program delivery.

Dissemination increases to the extent that an existing diffusion network is in place. Additional factors include whether credible community leaders advocate for the program and communicate with each other about the program, master trainers are available to model program implementation, and implementers feel empowered to spread the program.

As with effective prevention programs, most effective diffusion strategies are based on sound theories of behavior change, in this case, change in the behavior of communities, organizations, and community leaders. First among these is *diffusion of innovation theory*, which posits that a prevention program will be

more rapidly adopted if it is considered innovative and advantageous compared to other programs, and is easy to try out, implement, and adapt to existing settings. *Persuasion marketing theory* suggests that a prevention program will be more readily adopted to the extent that more people in a community are made aware of the program, for example, through positive media coverage. *Mass communication and communication network theories* suggest that the spread of positive interpersonal communications about a program from respected community leaders to the public will enhance adoption and implementation of that program. Finally, *organizational development and process theories* posit that coalitions of prevention leaders and implementers, alike, will increase in empowerment and promote implementation and dissemination of a prevention program to the extent that they are structured, have a clear decision-making process, accept responsibility for prevention tasks, and are recognized for their work.

### Settings for Program Delivery and Diffusion

Effective prevention programs are delivered and disseminated across a range of settings. The most effective settings or channels for prevention programming appear to be those that represent major day-to-day influences on youth drug use and drug use prevention. These include the school (teachers), the home (parents), mass media (television and news programmers), community organizations (either existing youth-serving organizations or new organizations developed for the express purpose of drug abuse prevention planning), and local school and community policy settings (school and community leaders). These settings also reflect targets for prevention in addition to youth. For example, parents who are targeted for parent-child communication skills training may increase positive family bonding, which in turn has protective effects on their children's drug use.

### School Programs

Most school programs are demand reduction prevention programs concentrating on universal prevention. Most of these are delivered by teachers, some with assistance of trained peer leaders. Fewer have focused on selective or indicated prevention programs, such as student assistance programs, or group behavioral skills training for failing or truant students.

Overall, school-based prevention programs have shown strong 1- to 3-year effects on monthly use rates of gateway drugs. Evidence-based programs that include more than seven sessions, include parent-child homework, and/or use booster sessions have achieved effects lasting up to 5 years. The magnitude of effect overall appears to be larger than that achieved from school health education programs that include tobacco or drug education, ranging from 20% to 67% net reduction in use compared to 7%. Whether the differences achieved from specific drug prevention programs versus health education are due to differences in teacher training, teacher or student motivation, or program novelty is not clear.

### Parent Programs

There are fewer parent-based and family-based prevention programs compared to school programs, perhaps due to the relatively greater difficulty in achieving large-scale and sustained parent participation in prevention. Evidence-based parent programs include universal, selective, and indicated programs. Few, however, focus solely on parents. Universal prevention programs include those that promote positive parent-child communication and bonding; take-home assignments as part of a middle school prevention program, media programming, or multicomponent community programs; and programs that promote parent involvement in school policy, and prevention support. All of these universal programs have shown relationships between parent participation in prevention and increase in parent-child communication.

Selective parent prevention programs have included those for disadvantaged parents, parents who report or are referred to these programs because of family management problems, and parents of students who exhibit early social or academic learning difficulties. Programs that include and change skills for family management, rule setting, and modeling of supportive behavior toward the child have demonstrated improvement in observed parent-child interactions and social behavior in school.

Indicated programs for parents of children with conduct and attention deficit disorders have focused on increasing positive parent-child interaction and working with educators to maximize child learning in school. Some of these programs had some effects on changing child aggressive behavior and attention in school, although effects on drug use and social and

academic competence vary by baseline problem behavior levels of children, gender, and length of time for effects to appear.

### Mass Media Programs

Evidence-based mass media programs include universal prevention programs targeted at a general adolescent population, advertising campaigns, and small-scale interventions involving exposure of high-risk youth to different types of counter-advertising, and antiuse campaigns aimed at the general youth population. Recent evaluations of national and state campaigns have shown changes in youth attitudes toward and intentions to use drugs. Local antiuse media programs and campaigns are effective in changing youth awareness of drugs, critical thinking about drug use messages, attitudes, and intentions. The magnitude of effect increases if messages are matched to youth preferences, for example, using high stimulus messages with youth who score high on sensation seeking. Media literacy programs that focus on reconfiguring ads and counter-advertising strategies have shown some short-term changes in adolescent attitudes toward drug use, intentions to use, and experimental use.

### Community Programs

Evidence-based community programs encompass skills training conducted in after-school or recreational settings, and community organizing efforts such as coalition development and youth activism. Resistance skills programs conducted in community settings, such as Boys and Girls Clubs, have shown significant short-term decreases in gateway drug use comparable to short-term decreases reported for school-based programs. Other community programs consist mainly of community organization for prevention. Organizational efforts have thus far shown small changes in drug use (usually changes of less than 1% in prevalence) but large changes in community leader prevention planning, participation, and empowerment. An exception is an organization that involves youth activism, which has produced significant changes in youth tobacco and alcohol use.

### Policy Programs

Most effective policy interventions concentrate on tobacco or alcohol policy change at the local level of

community or school. Some policy interventions involve educational programming for teachers, parents, and/or students. These interventions aim to increase awareness, support, implementation, and enforcement of existing policy. Others have involved increasing tobacco or alcohol taxation, restricting youth access to tobacco or alcohol, or youth activism to promote support for community policy. Overall, these policy interventions have shown decreases in adolescent tobacco and alcohol use for 1 to 3 years.

### Comprehensive, Multicomponent Programs

Adding components or multiple modalities to a prevention program may increase its impact, although the mechanism for the increase, for example, whether additional components provide a booster effect or simple repetition of prevention messages, is not well understood. Overall, results of school programs that included one or more additional program components have shown short-term effects on monthly smoking and drug use similar to those of comprehensive school programs that included a large number of sessions and boosters. However, effects of school plus community programs appeared to have a greater range of effects and larger long-term effects on heavier use rates, averaging 8% net reductions.

Combining parent involvement through education or homework with a school program increases effects on parent involvement and youth behavior and parent behavior. Effects of environmental interventions appear to be stronger to the extent that they are combined—for example, a community no-smoking ordinance with youth sting operations and mass media programming. Relative reductions of up to 20% in youth tobacco use prevalence have been achieved by combining community and youth activism to promote restricted access policy and local mass media support. Policy change, in conjunction with a school program, mass media campaign, community activism or organization, or multicomponent community program, has produced significant reductions in youth and young adult tobacco or alcohol use. Overall, multicomponent prevention programs that include a school program appear to have larger, more sustained effects than school programs alone.

A *comprehensive* community-based prevention program attempts to incorporate all the modalities that are hypothesized to affect youth drug use: school, parent, mass media, community organization, and

community policy. Using all modalities, usually in a staggered sequence rather than simultaneously, maintains novelty and interest by a community over the long term, increases the potential to change community social norms for drug use, and generally provides greater dose-response and booster effects than would be expected to occur from single or nonsequenced modality programs.

## ISSUES IN PREVENTION

The field of prevention intervention research is well advanced, with well over 200 published studies, reviews, and meta-analyses. The majority of these have reported the effects of school programs, followed by media and parent programs, community and policy interventions, and last, multicomponent programs and comprehensive community interventions. The number of studies available for each type of programming reflects the greater difficulty, time, and cost of mounting the more complex programs. Also because of these factors, studies that have systematically compared the effects of separate program components are limited. Thus, research on additive and interactive effects of different types of programs and program components is less advanced than studies of effects of separate programs.

In terms of types of prevention, more research has been reported on the effects of universal compared to selective and indicated prevention programs. Overall, the universal programs have been shown to be effective regardless of ethnic, demographic, or geographic factors. Currently, the available research on selective and indicated programs suggests that they are effective with different at-risk groups, whether in rural or urban settings, although there is some variation in effects with boys compared to girls.

The study of factors that promote use of effective prevention programs is relatively recent and is sometimes referred to as moving from science to practice or simply as action or Phase 5 (demonstration/diffusion) research. Identification and subsequent manipulation of these factors in large prevention trials will require greater role identification, cooperation, and mutual planning between researchers and practitioners than has previously occurred. This joint effort may result in reinvention of prevention programs that were originally tested and shown to be effective according to a certain standard. Little is currently known about the parameters of reinvention that will eventually

enhance widespread diffusion of prevention programs. Additional issues are the lack of systematic comparisons of different programs and program components that are assumed to have additive and synergistic effects, and comparisons of change in variables that are hypothesized to mediate program effects in effective prevention programs.

## FUTURE DIRECTIONS IN PREVENTION

Three major areas of prevention research are expanding, results of which are expected to translate into changes in prevention programming. The first is *prescriptive matching* of prevention programs to subpopulations or types of youth. Included in this area are tailoring role plays, messages, and delivery techniques to males versus females, aggressive versus nonaggressive youth, high versus low sensation-seeking youth, and youth from different cultures; and identification of youth who may be at high genetic risk for nicotine or other types of drug addiction, with the long-term goal of developing different prevention strategies for these groups. The second is including in prevention programming strategies to maximize adoption, quality of implementation, and diffusion. Included in this area are drug use epidemiology and prevention training for administrators to increase their knowledge about prevention programs, inclusion of videotapes to supplement in-person implementer training, and testing of alternative prevention training methods such as interactive distance learning through television. The third is the identification and promotion of prevention delivery and management systems that have potential for sustaining evidence-based programs for long periods of time.

## SUMMARY

Overall, the prevention literature indicates that most prevention programs are universal. Fewer programs have been systematically evaluated with high-risk or drug-using youth. Evidence-based programs tend to be based on theories of behavior change, and focus on either counteracting risk factors, promoting protective factors, or both.

Social influences prevention programs overall show the largest effects on youth drug use. Programs aimed at protective factors affect parent-child communication, bonding, and intentions to use drugs. Programs aimed at risk factors affect drug use resistance,

drug use, and intentions. Well-implemented school programs with boosters, as well as multicomponent community programs, appear to have more durable and generalizable effects across substances than other programs. New directions in prevention include matching prevention programs to subgroups of youth, building diffusion strategies into prevention programs, and promoting delivery and management strategies that will sustain prevention programming in field settings over the long term.

## DRUG CRAVING

---

There is no indisputable definition of drug craving. Lack of consensus centers on the multiple ways craving is conceptualized, whether craving has one or several meanings, and inconsistencies in measurement. No adequate animal models exist to guide human research. Some argue that it is a uniquely human experience. Craving is often cited as a reason for drug use, but the role of craving in the development of substance use disorders or in predicting relapse is unclear. Yet, orderly, intensity-related increases in drug craving have been found, suggesting that craving is not an all-or-none phenomenon, but rather should be viewed along a motivational continuum similar to drug response. Increased craving for one type of drug may also trigger craving for other drugs of abuse. Drug craving is also linked to increases and decreases in allocation of attention, sensory, perceptual, and memory

resources. A broad range of neurobiological systems have been linked to craving, but a common pathway through which it operates has yet to be identified. Inevitably, this splintering of the essence of drug craving in diverse directions has resulted in disagreement regarding its universal meaning. Thus, this entry provides a brief overview of the main areas of contention.

## MULTIPLE MEANINGS AND MEASURES

Drug craving is often defined as an irresistible urge that triggers use or relapse. However, it has also been described as unpleasant withdrawal symptoms, obsessive thinking about drug use, and wanting to reexperience the effects of a drug. Among clinicians, researchers, and drug users, the term may mean anything ranging from drug urges to liking, wanting, or needing drugs. Typically, craving is measured using one or a few items that tap into a general aspect of craving, such as rating the average intensity of current desire to use drugs on a 100-point scale. Using these measures, there is little distinction between craving and urge. However, discrepancies have been noted between drug craving as "a strong desire" and how users take the word to mean "any desire or urge, even a weak one, to use drugs." Other distinctions include wide variation in the frequency and duration of drug-craving episodes. Thus, there is potential added informational value in determining if drug craving has unique features, similar to irritability and dysphoria being distinct aspects of negative mood. For example, using several items with broader and more meaningful content coverage (multifactorial measures), four distinct aspects of craving for alcohol, cocaine, heroin, marijuana, and tobacco have been found: (1) inability to control use, (2) relief from withdrawal or negative mood, (3) positive benefits of use, and (4) urges and desire coupled with intention and planning to use drugs. Whether these aspects of drug craving are complementary and unique is an open question.

## EXPLANATIONS OF CRAVING

Drug craving can be viewed solely from a learning perspective, based on the notion that stimuli such as people, places, and things associated with drug use can acquire the properties of conditioned triggers (cue-reactivity) through repeated pairings with drug use. But, learning explanations of drug craving have proved inadequate and inconsistent. For one reason,

the sight of a cigarette may elicit responses that are pleasurable (drug-like) or painful (drug-opposite), depending upon whether one has no intention of stopping smoking or is trying to quit. Relief of depressive symptoms (negative reinforcement) does not explain the frequent lack of association between craving and withdrawal. Positive reinforcement (euphoria) fails to account for the fact that craving and use often persist despite enormous negative health consequences of continued drug use, such as increased risk of HIV infection from needle sharing.

Cognitive explanations of drug craving are equally plausible in that cue-reactivity may reflect priming of semantic networks related to users' need states (pleasantness-unpleasantness), a shift of focus from environmental cues to internal thoughts and feelings, or be mediated by a wide range of cognitive processes, including affect, expectations, and efficacy. For example, heart rate acceleration is commonly found during craving processing, which may reflect cognitive interference on concurrent problem solving (drug-use planning activities). Or craving may be associated with the incentive properties of positive outcome expectations ("I will feel better"), such as withdrawal situations in which there is little confidence in the ability to resist drug use. Brain imaging studies in humans support these cognitive explanations. Increases in drug craving have been associated with activation (increased glucose metabolism or blood flow) in the amygdala and anterior cingulate (emotionality), dorso-lateral prefrontal cortex (working memory), and orbitofrontal cortex (compulsive behavior, expectation of rewarding stimuli, and impaired judgment). Thus, drug craving may be associated with a range of difficulties other than drug use, such as reward deficiency syndrome (reduced ability to experience pleasure) or attention problems, including faulty novelty detection or behavioral inhibition deficits. No single explanation accounts for the widespread variation in these findings.

## IMPLICATIONS

The *Diagnostic and Statistical Manual of Mental Disorders (DSM)* defines craving as a strong subjective desire to use drugs, and states that most, if not all, persons with substance dependence crave to readminister drugs. Yet, drug craving is no longer a significant diagnostic indicator in *DSM*. Nevertheless, craving measures are sometimes used to evaluate substance use disorders, and urges and desires are often markers

for pathological use. Most accounts of craving assume there is a meaningful relationship between craving and drug use, but other approaches reject the notion that the motivational properties of urges and desires are necessary conditions for either continued use or relapse. Thus, the concept of craving has merited sufficient attention to be examined in isolation from use. Even the World Health Organization has recommended that evaluating craving reduction should follow strong criteria, because the aim of intervention is the treatment of drug craving, not merely drug use.

In this context, the notion of craving is recognized as a complex, multiply-determined phenomenon that may have cultural, social, and psychosocial dimensions measured optimally by multiple means. For example, drug craving may be influenced by language to the degree that translations have encountered problems in equivalency of meaning, such as the difference among ratings of drug craving taken "right now" and "ahora mismo," "un instante," or "en este momento," each bound to a distinct time frame. Given the level of complexity of the topic, it is not surprising that significant discoveries remain hampered by not having unambiguous measures with which to define craving universally for all commonly abused substances.

## EATING DISORDERS

---

Individuals with eating disorders can present a complicated clinical problem to health care providers. Severity can be extreme, with substantial risks to psychosocial and physical functioning. The complex etiology of eating disorders, combined with high rates of relapse for some disorders, have prompted considerable research. This is important, given the high rates in females but also increasing problems in children, males, and ethnic minorities.

This entry reviews the status of work on eating disorders by describing classification, diagnosis, epidemiology, etiology, and treatment. Anorexia nervosa, bulimia nervosa, and binge eating disorder are covered.

### DEFINITION AND DIAGNOSIS

In the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, four distinct eating disorders (ED) are classified: anorexia nervosa (AN), bulimia nervosa (BN), eating disorder not otherwise specified (ED-NOS), and the research category of binge eating disorder (BED). While some diagnostic features are similar, there are central characteristics of each disorder. *DSM-IV* criteria for each of these disorders are presented in Table 1.

#### Anorexia Nervosa

AN was the first eating disorder on the scene, with diagnostic criteria emerging in the 1970s. AN is

characterized by intense fear of weight gain and obsession with thinness, even when the individual is emaciated. Anorexic behaviors are attempts to decrease food intake through dietary restriction using methods like undereating, fasting, vomiting, and laxative use, or to increase energy expenditure through excessive physical activity. As a consequence, individuals with AN are significantly underweight. Other features often associated with AN (and semistarvation) include depressed affect, loss of sexual interest, withdrawal from social activities, poor interpersonal relationships, perfectionism, low self-esteem, and poor concentration.

Individuals with AN become overwhelmed by concerns about their bodies and immersed in strategies to lose weight or prevent weight gain. Especially salient are extreme restrictive behaviors, such as excessive exercise despite physical injuries, and behaviors that promote the appearance of having eaten food, such as hiding food from others, moving food around on their plate, or preparing elaborate meals for others. These behaviors are motivated by irrational fears of becoming fat. When attempts are made to intervene, individuals with AN may respond with anger, denial, social withdrawal, and manipulative behaviors.

#### Bulimia Nervosa

BN shares similarities to AN such as restrained eating and preoccupation with shape and weight, but individuals maintain a normal body weight, engage in objective binge episodes, and compensate for perceived calorie excess by vomiting, excessive exercise, or use of laxatives or diuretics. A binge is defined as

**Table 1** *DSM-IV Criteria for Anorexia Nervosa, Bulimia Nervosa, Binge Eating Disorder, and Eating Disorder Not Otherwise Specified*

*Anorexia Nervosa*

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
- B. Intense fear of gaining weight or becoming fat, even though underweight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- D. In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

*Specify type:*

**Restricting Type:** during the current episode of Anorexia Nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

**Binge-Eating/Purging Type:** during the current episode of Anorexia Nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

*Bulimia Nervosa*

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  - (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
  - (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of Anorexia Nervosa.

*Specify type:*

**Purging Type:** during the current episode of Bulimia Nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

**Nonpurging Type:** during the current episode of Bulimia Nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

*Binge Eating Disorder*

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  - (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
  - (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. The binge-eating episodes are associated with three (or more) of the following:
  - (1) eating much more rapidly than normal
  - (2) eating until uncomfortably full
  - (3) eating large amounts of food when not feeling physically hungry
  - (4) eating alone because of being embarrassed by how much one is eating
  - (5) feeling disgusted with oneself, depressed, or very guilty after overeating
- C. Marked distress regarding binge eating is present.
- D. The binge eating occurs, on average, at least 2 days a week for 6 months.
- E. The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise) and does not occur exclusively during the course of Anorexia Nervosa or Bulimia Nervosa.

(Continued)

**Table 1** (*Continued*)*Eating Disorder Not Otherwise Specified*

The Eating Disorder Not Otherwise Specified category is for disorders of eating that do not meet the criteria for any specific Eating Disorder. Examples include:

1. For females, all of the criteria for Anorexia Nervosa are met except that the individual has regular menses.
2. All of the criteria for Anorexia Nervosa are met except that, despite significant weight loss, the individual's current weight is in the normal range.
3. All of the criteria for Bulimia Nervosa are met except that the binge eating and inappropriate compensatory mechanisms occur at a frequency of less than twice a week or for a duration of less than 3 months.
4. The regular use of inappropriate compensatory behavior by an individual of normal body weight after eating small amounts of food (e.g., self-induced vomiting after the consumption of 2 cookies).
5. Repeatedly chewing and spitting out, but not swallowing, large amounts of food.
6. Binge-eating disorder: recurrent episodes of binge eating in the absence of the regular use of inappropriate compensatory behaviors characteristic of Bulimia Nervosa.

Note. From American Psychiatric Association. (1994). *Diagnostic and statistical manual of mental disorders* (4th ed.). Washington, DC: Author. Copyright 1994 by the American Psychiatric Association. Reprinted by permission.

eating an unusually large amount of food given the circumstances, combined with feelings of loss of control.

BN is often described using the binge-purge cycle, in which social pressures on women to be thin lead to preoccupation with food and attempts to control weight through restrained eating. Over time, extreme restriction cannot be maintained and triggers binge eating, with the compensatory purging behaviors emerging to offset the increased food intake. Purging reinforces binge eating by reducing anxiety about weight gain and disrupting learned satiety cues.

Most bulimic episodes occur in private and are often planned; individuals choose a time and place where they can eat binge foods in secret. People typically binge on foods they deny themselves when dieting, most often foods high in fat and sugar. Bulimic episodes may be precipitated by anxiety, fatigue, negative affect, boredom, or food cues. Once this pattern is established, it becomes a self-perpetuating cycle. Features of BN include depression, low self-esteem, and substance use. Approximately 25% of patients with BN have a history of AN.

### Binge Eating Disorder

BED was introduced in the *DSM-IV* as a psychiatric disorder in need of further study. While BED falls in the ED-NOS category of *DSM-IV*, research suggests it should be a separate diagnosis. Binge eating is a central feature of BED, but unlike BN, individuals do not purge. About half of individuals with BED are overweight or obese. Approximately 50% of

individuals with BED report bingeing prior to the onset of dieting, 40% report the reverse, and 10% to 15% begin dieting and bingeing simultaneously. Preliminary work suggests that 2% to 5% of people with BED have a history of AN, and 5% to 10% have a history of BN.

### Eating Disorder Not Otherwise Specified

Atypical eating disorders not meeting criteria for AN or BN are classified as eating disorders not otherwise specified (ED-NOS). A diagnosis of ED-NOS does not suggest subclinical severity or absence of impairment. These atypical eating disorders are typically diagnosed when individuals do not have one or more essential features of an eating disorder. An example would be an individual who meets all criteria for AN but has normal menstrual cycles. Other atypical eating disorders may be less similar in their presentation to AN or BN. This might include psychogenic overeating or vomiting, chronic dietary restraint combined with overexercising, or recurrent binge eating with low levels of purging behaviors.

### EPIDEMIOLOGY

Eating disorders occur primarily in developed, industrialized countries, with young females the most vulnerable population. Although AN and BN have traditionally been described as Western disorders that affect mostly Caucasian women, countries such as Asia, India, and Africa have documented disordered eating patterns. BED may be as prevalent among

African American and Hispanic women as it is among Caucasian women. Racial differences in clinical presentation of BED argue for culturally sensitive assessment.

Both AN and BN typically emerge in adolescence, with few cases beginning in adulthood over age 25. Most individuals present with BED at a later age than AN and BN, with symptoms beginning primarily in adulthood and with a typical age of onset between 30 and 50 years old.

The population prevalence of AN appears to be approximately 0.28% and 1.0% for BN. Although no studies have documented increases in AN in the general population, research in college populations has indicated increased rates of 5% to 15% for eating disorders. As many as 19% of female students report symptoms of BN, but criteria vary widely across studies. It is likely that many more females experience serious eating problems but may not satisfy formal diagnostic criteria. As many as 80% of female college students report binge eating. Community-based research suggests that BED occurs in approximately 2% to 3% of adult populations and 8% of obese populations. Among individuals seeking treatment for weight control, prevalence rates appear much higher and range from 15% to 70%.

Males represent 5% to 10% of eating disorder cases in clinical samples; some studies suggest prevalence rates as high as 10% to 15% in the general population. In contrast to AN and BN, which affect females primarily, BED is more evenly distributed across the genders, with as many as 40% of cases in males.

Children are increasingly displaying symptoms of eating disorders. Childhood-onset eating disorders typically occur between ages 7 and 13, with boys representing 20% to 25% of cases. There are not sufficient data on incidence and prevalence, and it remains uncertain whether children appropriately fit existing diagnostic systems.

## PSYCHOLOGICAL AND MEDICAL CONSEQUENCES

Eating disorders are associated with comorbid psychopathology, lower quality of life, reduced self-esteem, poorer social relationships, and dysfunctional attitudes about shape and weight. About one third of persons with AN have a major depressive disorder currently, and 60% have had depression previously. Anxiety disorders such as obsessive compulsive disorder

and social phobia are as common as depression, and personality disorders are comorbid in approximately 40% of AN cases. BN is also associated with high levels of lifetime (50%) and current (20%) major depressive disorder, substance abuse (25%), and Cluster B and C personality disorders (40%).

Although less is known about comorbidity with BED, it appears that these individuals have higher rates of major depressive disorder (up to 55%), substance use, anxiety disorders, and personality disorders such as histrionic, borderline, and avoidant personality disorder. Research also indicates that people with BED have problems related to perfectionism, ineffectiveness, and low interoceptive awareness.

Adverse medical conditions associated with AN and BN are many, and include osteoporosis, nutritional deficiencies, cardiovascular problems (including congestive heart failure), and poor cognitive function. Because medical complications of eating disorders most often arise from extreme dietary restriction and purging behaviors, there is substantial overlap in the medical consequences of AN and BN.

As a result of inadequate food intake and purging behaviors, common medical complications include serious disturbances of fluid homeostasis and electrolyte abnormalities. Renal electrolyte abnormalities often occur from purging, with the most serious condition being hypokalemia, which may cause cardiac arrhythmias (a primary cause of death from eating disorders) and cardiomyopathy. These consequences are due to potassium depletion from frequent purging. Cardiovascular abnormalities are common in individuals with AN and BN, such as low blood pressure, hypotension, and sudden death due to ventricular arrhythmias. Gastrointestinal complications can also occur, such as esophagitis, gastric dilatation, dyspepsia, and gastroesophageal reflux disease. For individuals with ED who use laxatives, colon problems often surface with symptoms similar to irritable bowel syndrome, as well as colonic dysmotility and poor peristaltic function.

Endocrine abnormalities are frequently found in individuals with AN, and to a smaller degree in those with BN. Dysfunction resulting in the endocrine system can include abnormalities in the hypothalamic-pituitary axes, resulting in irregular menses, hypercortisolism, abnormal thyroid functioning, hypoglycemia, and diabetes mellitus.

More visible signs of an eating disorder are very low weight in AN and dental complications such as

enamel erosion and dry mouth, as well as glandular swelling and calluses of the hand resulting from repeated vomiting. Nonspecific symptoms reported with BN include weakness, fatigue, and tiredness, as well as physical symptoms of swelling hands and feet, abdominal bloating, headache, and nausea. Among those with AN, starvation may frequently result in dry skin, loss of scalp hair, brittle nails, and development of fine facial hair.

Medical conditions associated with BED are primarily related to obesity, as many individuals with BED are obese. The most common diseases associated with obesity include coronary heart disease, hypertension, diabetes, gallbladder disease, some cancers, sleep apnea, and degenerative joint disease.

The medical consequences of eating disorders have serious implications for mortality and morbidity. Mortality rates for AN are significant (approximately 6% per decade of illness). This is the highest mortality rate of any psychiatric disorder in young people, with death resulting from both physical complications and suicide. The crude mortality rate for BN is 0.3%, the lowest of eating disorders.

## ETIOLOGY

Eating disorders have a complex etiology with multiple determinants, including cultural, social, biological, familial, developmental, personality, and cognitive factors. These risk factors are not independent, and the nature of their specific interactions is unclear.

### Causes of Anorexia

#### *Nervosa and Bulimia Nervosa*

##### *Sociocultural Factors*

Eating disorders exist primarily in countries with abundant food and extreme pressure to be lean. Western media perpetuates the importance of thinness, glorifies underweight body types, and encourages unrealistic expectations for female physical attractiveness. Comparisons of blind versus sighted women indicate that visual media, such as the viewing of fashion magazines and television, contributes to negative eating attitudes and body dissatisfaction. Exposure to slim body types increases body dissatisfaction in women. Thus, many women feel distressed about their weight and shape, which leads to dieting.

Peer groups may also perpetuate risk, especially among adolescent females. Peers can exert their

influence by focusing on shared concerns about weight and body shape. Bullying and teasing about weight is also related to body dissatisfaction and eating concerns, especially in preadolescent and early adolescent peer groups.

##### *Psychological Factors*

The comorbidity of depression and anxiety with eating disorders raise questions of sequence. Most studies show that these disorders predate the eating disorder. Furthermore, negative affect appears to mediate the relationship between dieting and binge eating and may also be relevant in the binge-purge cycling of BN. Bingeing may be a way of elevating mood initially, but guilt and shame typically follow. Purging partially eliminates excess calories, but can also relieve negative emotions and reduce tension. This is consistent with reports of BN patients who indicate lower levels of depression and anxiety following the binge-purge occurrence.

Low self-esteem is another general risk factor for psychopathology that increases vulnerability to eating disorders. Self-esteem based on shape and weight is worse among patients with eating disorders. Low self-esteem predicts onset of disordered eating and worse outcome. Self-esteem moderates perfectionism in predicting symptoms of BN, and interventions aimed at increasing self-esteem have reported lowered incidence of eating disorder symptoms at 1-year follow-up.

Personality disorders and substance abuse are commonly associated with eating disorders. Estimates of comorbid personality disorders range from 42% to 75% of cases of eating disorders. BN has been associated with Cluster B and C disorders such as borderline and avoidant personality disorders, and AN with Cluster C disorders such as obsessive-compulsive and avoidant personality disorders. The presence of personality disorders may increase the likelihood of additional mood or substance abuse problems. Substance abuse has been found in 12% to 18% of cases of AN and 30% to 37% of those with BN.

Body dissatisfaction is a central factor because of its association with negative affect, low self-esteem, and dieting. Body dissatisfaction is believed to cause dieting, which is a precursor to binge eating. Many different risk factors for eating disorders may also operate through body dissatisfaction, such as media exposure or peer teasing about weight.

Several cognitive risks are important to eating disorders. Most individuals with ED obsess about eating, weight, and shape. Research shows that three quarters of ED patients are preoccupied with weight and food for more than 3 hours per day, with 50% reporting that they could not control the preoccupation. Perfectionism is a consistent characteristic in people with eating disorders, especially AN (most evident in the need to have perfect appearance).

Certain negative life experiences may join the list of risk factors. Sexual abuse may be one such experience. A number of studies have documented correlations with previous sexual abuse and eating disorders, but it is uncertain whether sexual abuse is a specific risk factor for eating disorders or a more general risk factor for psychopathology.

### *Puberty*

Adolescence involves many physical and psychosocial adjustments. Average body fat in adolescent females increases from 8% to 22%, with fat deposition occurring mainly in the abdomen, thighs, and buttocks. Cultural messages mandate that these body parts be thin, small, and toned, which exacerbates body dissatisfaction in females. The emergence of dating relationships and the need for peer acceptance during puberty may further increase risk for ED, where girls can become vulnerable to dietary restriction and weight control methods to gain acceptance by peers or to feel physically attractive to males.

### *Familial Factors*

Correlational research on family factors suggests that parents may play a role in increasing risk for ED. Research has described the family environment of individuals with ED to include hostility, enmeshment, and abnormal attachments between parents and children. Patients with ED typically report greater parental intrusiveness, control, and criticism, and perceive their parents to have extreme concerns about achievement and appearance.

Maternal influences may be particularly important. Mothers of patients with ED are more likely to criticize their children's weight or shape, encourage them to lose weight, and are themselves more likely to be engaging in eating-disordered behaviors and dieting. Mothers may also increase risk by transmitting cultural values about shape and weight, making direct

comments about their child's weight, and through feeding practices such as using food to control or reward behavior.

Prospective studies are needed to determine the extent to which parental behaviors are causal, and if they are, to separate the effects of children modeling parental behavior from those of parents displaying unhealthy attitudes toward a child's weight and eating.

### *Genetic Risk Factors*

The role of heritable factors in the etiology of ED has received increasing attention, although the particular mechanism of genetic transmission is not clear. Results from family, twin, and molecular genetic studies of AN and BN suggest that genetic effects may play an important role in disordered eating. Family studies have reported as much as a twelvefold increase in the prevalence of these EDs among relatives of individuals with AN and BN compared to controls.

Twin studies have documented strong concordance in monozygotic twins for both AN and BN, with genetic factors accounting for 50% to 80% of the variance. Other research has found that 32% to 72% of variance in eating disorder attitudes (such as body dissatisfaction and weight preoccupation) are attributable to genetics. Molecular genetic research has identified gene markers of the development of AN and BN, with serotonin being highlighted. In particular, levels of 5-hydroxyindoleacetic acid (HT) appear to be increased in patients with ED. The role of serotonin is not clear, and further study is needed to address the involvement of additional neurotransmitter systems in the pathogenesis of ED, such as those affected by dopamine-related genes.

Heritable characteristics of ED may overlap with the genetic transmission of other depressive and anxiety disorders. Because both ED and attitudes related to shape and weight may run in families, research is needed to distinguish the occurrence and impact of these different vulnerability factors.

### *Causes of Binge Eating Disorder*

The risk factors for BED are less clear. BED affects a more heterogeneous population than does AN or BN, and the age of onset occurs later in adulthood. BED affects both women and men, and both Caucasian and minority cultures. It is likely that biological, psychological, and environmental factors

combine to increase risk of developing BED. Because research on risk for BED is still in its infancy, several potential risk factors are described here, although it is premature to conclude that these factors accurately or sufficiently explain etiology.

### *Obesity*

Childhood and adult obesity appear to increase the probability of engaging in dieting, which may in turn increase vulnerability to binge eating. Having a parent who is obese increases the biological risk for obesity.

### *Parental Influences*

Living with obese parents may promote eating habits that increase vulnerability to BED. For example, unhealthy eating habits and sedentary lifestyles of parents may lead children to adopt the same practices. Parental concerns about a child's overweight status can lead to excessive restriction of food intake in which children are not allowed to eat certain foods, which can inadvertently encourage bingeing on these forbidden foods in private.

Affective disorders in parents may also increase vulnerability to BED, especially if parental mental illness negatively affects the parent-child relationship. One study assessed multiple risk factors of BED and found that individuals with BED reported higher levels of lifetime parental depression and parental criticism about weight and shape, and lower parental contact and affection than controls.

### *Weight Cycling*

Dieting appears to be a risk factor for some, but not all, individuals with BED. Some research suggests that there may be two different subtypes of BED: those who begin dieting prior to the disorder and those who binge first. Levels of psychopathology may be higher among those who begin dieting first, but more research is needed to better understand the distinction between these subtypes. There may also be elevated rates of weight cycling (repeated weight losses followed by weight regain) among individuals with BED. Research is needed to determine how to best measure weight cycling and to determine whether objective repeated weight losses and gains, or self-perceptions of repeated dieting attempts, play a stronger role in the etiology of BED.

### *Psychological Factors*

Many studies have documented higher levels of psychopathology in obese binge eaters compared to nonbinge eaters. Disorders that appear to be prevalent in individuals with BED include depression, anxiety, panic disorder, BN, and borderline, histrionic, and avoidant personality disorders. There is insufficient research to determine an accurate prevalence of these forms of psychopathology among individuals with BED. However, there are consistent estimates that rates of affective disorders (primarily major depression) occur in approximately 50% in people with BED. Depression may play a particularly important role as a trigger for or consequence of binge eating. Binge eating may mediate the relationship between obesity and psychopathology, but the nature of this process is not yet clear.

Certain additional personality characteristics have been reported among individuals with BED. Binge eating has been associated with high levels of perfectionism and ineffectiveness, as well as higher levels of depressive cognitive styles.

Medications that cause weight gain may also be important in the development of BED. Although no studies have examined the risk of BED following the use of medication, individuals may become distressed about weight gain and begin dieting, which can then lead to binge eating.

### *Specific Life Events*

Because of the link between increased weight, dietary restraint, and binge eating behaviors, life events that lead to weight gain may play a role in the etiology of BED. The postpartum period may increase vulnerability for BED among women, especially for those who do not lose weight gained during pregnancy. Several studies have documented increased body dissatisfaction, dietary restraint, and concerns about weight and shape in postpartum periods, with some women developing clinical eating disorders. No research has examined rates of BED onset during this time period, which is an important question to address in future work.

Recovery from substance abuse may increase vulnerability to BED. Weight gain is common during such recovery, as individuals may substitute food for discontinued alcohol or drugs to cope with negative affect. No research has addressed this issue, so the frequency of substance abuse recovery leading to BED

has not been documented. Limited work indicates that substance-related disorders may be more common in men than women at risk for BED. Additional research is needed to clarify this finding and to examine other gender differences in risk factors.

## TREATMENT OF EATING DISORDERS

### **Bulimia Nervosa**

Different treatment methods have been evaluated for BN. Cognitive-behavioral therapy (CBT) has been the most extensively studied. It is consistently successful in improving all central features of BN, including reduction in bingeing, purging, dietary restraint, maladaptive cognitions about weight, and associated psychopathology. This treatment aims to normalize eating patterns, identify triggers for bulimic episodes, teach cognitive and behavioral skills to cope with bingeing and purging, and reduce maladaptive thoughts about shape and weight. CBT results in an average of 80% reduction in binge eating and a cessation rate of 40% to 50%, with improvements maintained at a 1-year follow-up.

Interpersonal therapy (IPT) is the only other psychological treatment to show comparable outcomes for BN. IPT was developed as a treatment for clinical depression, and helps patients identify and improve problems with interpersonal relationships. IPT for BN addresses interpersonal events that trigger bingeing and purging episodes. Some research comparing CBT and IPT indicates that IPT may have less effective short-term outcomes than CBT but comparable outcomes at 1-year follow-up. Both CBT and IPT are short-term outpatient treatments that typically involve 15 to 20 individual treatment sessions. Group treatment formats are also common.

Unlike AN and BED, medication treatment may be effective for BN. Evidence from medication trials indicates that antidepressants have the most clinical utility in treatment of BN and are superior to placebo in reducing binge eating, improving mood, and altering concerns about weight and shape. A range of antidepressant drugs can improve symptoms of BN, and there is no indication that certain antidepressants are more effective than others. Although the short-term benefits of antidepressants for BN are well established, their long-term impact is not clear. CBT in combination with medication can be effective and may enhance favorable outcomes compared to CBT alone. Antidepressant

medication may also be helpful for patients who relapse following treatment.

### **Anorexia Nervosa**

In contrast to numerous research studies on treatment for BN, the literature on AN is smaller and inadequate, with few controlled studies. While inpatient hospitalization is required for severely underweight patients, improved outcomes seem to result when treatment strategies are combined, typically including weight restoration with individual and family psychotherapies. Outcomes of controlled studies show little effectiveness of CBT in the treatment of AN. Some behavioral interventions have been effective in promoting short-term weight gain, but CBT does not appear to improve outcomes over alternative forms of treatment. Direct comparisons between CBT and other psychotherapies for AN are needed.

Several controlled trials of family therapy have demonstrated both short- and long-term effectiveness for AN, particularly in adolescents. The focus of this treatment often includes parent-directed refeeding of the adolescent and providing parental support to help the patient reclaim control and independence in his or her life. Research suggests that family therapy may have improved outcomes for individuals with a short history and early onset of AN, but may be of little help to patients with later onset and more severe illness.

There is little consistent evidence that medication helps with AN, despite the numerous psychological and biological problems related to this disorder. There have been few controlled medication trials, and no medication stands above others in improving symptoms. Medication treatment may be more relevant for related clinical features of the disorder, such as severe depression.

A variety of treatments may be required to treat this severe and complex disorder. Outpatient therapy can have high dropout rates, and a large percentage of individuals with AN continue to have disturbed eating and body image following treatment. Follow-up studies suggest that about 44% of patients have good outcomes of weight restoration and return of menses, but many continue to have psychiatric symptoms. Poorer prognosis exists for individuals with lower initial body weight, purging behaviors (especially vomiting), poor response to previous treatments, and disturbed family relationships.

## Binge Eating Disorder

The lack of research on BED leaves much to be known about the effectiveness of specific treatments. Cognitive-behavioral therapy, modified from CBT techniques for BN, has been tested most. Its focus is on changing maladaptive attitudes and behaviors related to binge eating, identifying binge triggers, moderating food intake, addressing negative stereotypes of overweight, and increasing weight control behaviors. In several studies, CBT has resulted in abstinence of binge eating in about 50% of patients, with longer-term research demonstrating efficacy of 60% at 1-year follow-up.

Interpersonal psychotherapy for BED has also been examined. IPT focuses on binge eating as an unhealthy strategy used to cope with negative emotions related to difficulties in interpersonal relationships. This treatment aims to change the interpersonal environment in which the binge eating was established and sustained. Two controlled studies have indicated effectiveness of IPT, and preliminary research suggests that CBT and IPT may have equivalent short- and long-term effects on binge eating and related psychopathology.

As many as two thirds of patients with BED who are treated with CBT or IPT achieve complete remission, but these psychological treatments do not produce weight loss. Another treatment option may be behavioral weight loss treatment (BWL), which results in both reduced binge eating and short-term weight loss. The focus of BWL is weight reduction through increased physical activity, lowered calorie intake, nutrition education, and attitude change. The low cost and amenability to wide dissemination of BWL are desirable, but it is not known whether weight lost is regained in patients with BED treated with BWL.

Few studies have evaluated medication for BED. Studies have demonstrated short-term benefits of antidepressants compared to placebo, but relapse rates appear as frequent with medication as with other psychological treatments. Medication alone may be insufficient to treat BED. Research is needed to test the efficacy of medication in conjunction with psychological treatments and the impact of long-term medication use.

## CONCLUSIONS

Eating disorders are severe, even to the point of being life-threatening. Anorexia nervosa has a significant

mortality rate, and the obesity associated with BED carries substantial risk for diabetes, heart disease, cancer, and other serious diseases. The psychological and social consequences can also be severe and are what typically bring patients with BN and BED to treatment (medical concerns are more often the predominant issue with AN). That the prevalence of these disorders is increasing is a major concern, as is the finding that children, males, and members of minority groups join women in being affected.

Considerable work has been done to identify factors that place individuals at risk for eating disorders. A combination of genetic, psychological, social, and family factors appear to interact in ways that make some individuals particularly vulnerable. Much more research is needed, however, to isolate specific causes.

Great progress has been made in treatments for the eating disorders. Anorexia nervosa remains a very difficult problem, even when combining many forms of treatment, and relapse rates are high. Bulimia nervosa and, to some extent, BED, respond much more readily to existing treatments. While medications have some benefit, the treatment of choice for BN and BED appears to be cognitive-behavioral therapy, with interpersonal psychotherapy also a viable choice. As with most complex clinical problems, prevention might be more effective than treatment in reducing prevalence, but far too little work on prevention has been done.

## ECOLOGICAL MODELS: APPLICATION TO PHYSICAL ACTIVITY

---

Ecological models of health promotion emphasize that health behavior is influenced by a variety of variables operating at multiple levels—ranging from intrapersonal factors (e.g., biological, cognitive, motivational) and interpersonal factors (social norms, supports, and networks) to broader sociocultural and organizational influences and macrolevel policy and environmental influences. Ecological models imply that behavior change interventions are more likely to be effective if they operate on multiple levels: combining “downstream” individually oriented interventions with “mainstream” interventions that reach entire populations through work sites, health plans, schools and communities, and “upstream” policy and environmental changes that work at the broadest possible levels to strengthen the norms, supports, and opportunities for healthful behaviors. Ecological models have helped health behavior change researchers understand the need for multilevel broad-spectrum health promotion strategies, and the models have brought the power of environmental and policy interventions working at the institutional, community, and broadest societal levels into sharper focus. Applied successfully to comprehensive tobacco control, ecological models are now being applied to the challenge of raising population levels of physical activity.

Ecological models are especially well suited to understanding the causes of the mass phenomenon of inactive lifestyles and guiding the development of effective strategies for promoting more active living for whole populations. The fact that only 25% of adults in the United States are engaging in the recommended amount of physical activity (i.e., 30 minutes of moderate intensity activities 5 or more days/week or 20 minutes of vigorous activity 3 or more days/week) and nearly half of America's youth are not vigorously active on a regular basis create an urgent need for effective population-level interventions beyond those requiring active decision making by individuals. Physical activity researchers have turned to ecological models because the more commonly used psychosocial models have not led to a thorough understanding of the influences on physical activity or to highly effective intervention strategies. Low levels of physical activity in industrialized nations have been attributed to the cumulative effects that technology (e.g., autodependent transport, more sedentary jobs and recreation) and our built environment have had on engineering physical activity out of daily lives. Ecological models are uniquely able to identify policy and environmental influences with the potential to raise physical activity levels in entire populations and prevent related health problems. In this entry, we focus on the policy and physical environmental levels of influence on physical activity to demonstrate the unique contribution of ecological models.

## CONCEPTS AND RESEARCH FROM THE BEHAVIORAL AND HEALTH SCIENCES

In applying ecological models to physical activity, the earliest work focused on developing hypotheses about specific policy and physical environmental variables that may influence behavior. One major category is the natural environment, consisting of such variables as weather and geography. However, factors related to the built environment attracted greater interest because of the potential to intervene. Behavioral and health scientists have been interested mainly in leisure-time physical activity, so most of the studies focused on recreational environments. A small literature has produced some consistent findings. Access to activity facilities, opportunities for physical activity (such as nearby programs), and aesthetic qualities of neighborhoods (enjoyable scenery) were consistently related to adults' physical activity. There was less

evidence that weather and safety concerns were related to physical activity, but these variables have not been studied often. For children, time spent outdoors and access to play areas were strongly associated with physical activity.

After reviewing the available intervention studies, the CDC Community Preventive Services Task Force concluded there is evidence to support a strong recommendation to create, or enhance access to, places for physical activity, combined with information outreach about these opportunities, as a way to increase physical activity. The interventions reviewed included efforts of work sites and communities to provide greater access to facilities like fitness centers or walking and biking trails.

Characteristics of buildings themselves may be related to physical activity, and it is important to understand such influences because people spend so much time indoors. Many buildings are designed with attractive elevators visible upon entry, but stairwells are hidden and unappealing. Numerous intervention studies have shown that signs promoting stair use or improving the aesthetics of stairwells can increase stair use. The evidence was strong enough for the CDC Community Preventive Services Task Force to recommend the use of "point-of-decision" prompts placed by elevators and escalators to motivate people to use nearby stairs. Other building-related strategies that may increase daily physical activity levels include slowing elevator speed to promote stair use, placing high volume "destinations" like copy centers or cafeterias in locations that require more walking, locating fitness centers within buildings, creating walking trails near buildings, and making wider use of parking lots that are not adjacent to buildings. Although each strategy might make only a small contribution to daily physical activity, they would be steps toward reengineering physical activity back into daily routines.

Policies include laws, regulations, and rules, and they can play multiple roles in influencing physical activity. Policies guide how the built environment is developed, and new policies are required to change most physical environmental variables. Other policies provide incentives or disincentives for physical activity. For example, most employers reimburse work-related travel by car but not by walking or cycling. Still other policies affect access to physical education and physical activity programs. Budgets for recreation departments or physical education are policies that affect access to physical activity programs. The CDC

Community Preventive Services Task Force found evidence to justify a strong recommendation for policies that supported required school physical education classes that increase the amount of time students spend in moderate or vigorous physical activity. Although virtually no health insurance plans in the United States reimburse physicians for counseling patients about physical activity, a small number of plans subsidize their clients who join health clubs, reducing important financial barriers. Organizations or agencies that control policies affecting physical activity resources or programs can be engaged in change efforts.

In summary, behavioral and health science researchers have identified a small number of environmental and policy variables that are related to physical activity, but there are many more hypothesized associations that have not been studied. Intervention studies on promotion of stair use, physical education, and improving access to programs have begun to influence national recommendations regarding the promotion of physical activity.

## CONCEPTS AND RESEARCH FROM NONHEALTH DISCIPLINES

Ecologically based research on physical activity has stimulated new transdisciplinary collaborations, particularly with urban planning and transportation professionals. These partnerships have produced new theoretical formulations and expanded research methodologies. Planners and transportation researchers have been studying how land use, community design, and transportation systems can affect walking and cycling for transportation as alternatives to automobile dependence. This is a different subset of physical activity than typically has been of interest to health scientists.

There is consistent evidence that the design of communities is related to transportation-related physical activity. The concept of the walkable neighborhood has proven useful. Walkable neighborhoods are those in which stores and jobs are located near homes (mixed land use), there is a higher density of residents to support the shops, and streets are on a grid pattern so there are direct routes from place to place (connectivity of streets). Availability of sidewalks, access to mass transit, less motor vehicle traffic, slower traffic speeds, bicycle lanes, and pedestrian signals are additional factors believed to encourage walking and cycling for transportation. Walkable neighborhoods tend to be in central

cities and older parts of towns that were developed before automobile transportation became so dominant. Most suburban neighborhoods are considered low in walkability, because they were designed to accommodate the needs of cars rather than pedestrians. The studies consistently show people do more walking and cycling for transport in walkable neighborhoods compared to less walkable neighborhoods. The difference has been estimated at about 30 minutes of physical activity per week. It will be necessary to change zoning laws (policy) to create more walkable neighborhoods (environment), but such changes could affect physical activity levels of large numbers of people on a relatively permanent basis.

In summary, researchers outside the health and behavioral sciences have shown how community design and transportation systems have created environments that have reduced daily physical activity for many people. Public and private research funders are increasingly setting aside funds to support transdisciplinary research on environments, policies, and physical activity.

## SUMMARY AND CONCLUSIONS

The defining feature of ecological models is the principle of multiple levels of influence on behavior. The vast majority of research has been on the intrapersonal and interpersonal levels of influence on health behaviors, but a rapidly growing literature from several fields demonstrates that many physical-environmental and policy factors are associated with physical activity. Thus, the research shows that only multilevel models are adequate to explain physical activity and lead to the development of effective interventions for increasing physical activity populationwide that have an optimal mix of downstream, mainstream, and upstream approaches. When community environments are made more activity friendly, then individually oriented and organizationally mediated (work site, school, health plan) interventions based on more traditional psychosocial theories and models are likely to be more effective in promoting and maintaining healthful levels of physical activity.

## ECOLOGICAL MOMENTARY ASSESSMENT

---

Ecological Momentary Assessment (EMA) is a method used in the health and behavioral sciences to study a range of phenomena as they happen in people's daily lives outside the laboratory setting. EMA is a valued method because it fills a unique niche. It is *Ecological*, involving multiple, immediate reports of subjective experiences (such as well-being, pain), behaviors (smoking), and/or physiological functioning (blood pressure, cortisol levels) as they occur within people's naturalistic environments. In this way, EMA avoids some of the limitations associated with assessing complex phenomena within a typical laboratory environment, such as the lack of generalizability to real-world situations. It is also *Momentary*. Phenomena are recorded as they are happening at a particular moment in time, rather than later from memory. Thus, EMA avoids many of the biases that come with retrospective accounts of experiences (for a discussion of these biases, see Stone, Shiffman, & DeVries, 1999). Finally, EMA is a versatile form of Assessment. It yields multiple reports per person over time, allowing researchers to examine patterns of data at both the individual and group level. In this respect, EMA is well suited to modeling change or covariation of phenomena over time. For example, simultaneous monitoring of people's experiences and their physiological functioning can identify how physical states respond to the stressors of everyday life.

Pioneering early EMA work were psychologists Mihalyi Csikszentmihalyi and colleagues who introduced a method in the late 1970s to investigate the stream of psychological experience in everyday circumstances. This novel approach, termed the Experience Sampling Method (ESM), used electronic pagers to signal people at random times during the day, at which point they completed a questionnaire on their thoughts, feelings, activities, and other measures of optimal experience or "flow." This work led to a number of experience-sampling applications in the field of psychology and, later, the health and medical sciences. Integral to this latter application were technological advances in portable sampling equipment such as lightweight blood pressure cuffs that allowed researchers to investigate the dynamics of physical functioning in everyday life. With these advances, Arthur Stone and Saul Shiffman coined the term

*ecological momentary assessment* to describe the study of all phenomena, both psychological *and* physical, in a situated and momentary fashion. In this way, EMA is a broader term than the Experience Sampling Method, which refers exclusively to the study of experiential phenomena.

EMA is both methodologically and technically challenging. In addition to the standard array of issues that beset any empirical study, EMA brings with it unique design, implementation, and analysis issues. EMA designs vary in the timing and number of signaled reports (see Reis & Gable, 2000, for a thorough discussion of design and analysis issues) as well as the types of portable technology used to obtain reports. Some studies employ inexpensive pagers or watches with programmable alarms that signal participants to complete a paper-and-pencil questionnaire about their psychological events. Other studies use the more expensive palmtop computers or personal data assistants (PDAs), which combine the signaling and recording needs into one system without the need for separate paper-and-pencil questionnaires (also see Feldman, Barrett, & Barrett, 2001). The use of palmtop computers or PDAs has the additional advantage of ensuring that people make their reports when signaled and not later from memory. Studies involving the study of physical functioning, such as blood pressure, require additional devices to measure these states in an ambulatory fashion. Last, because EMA yields large amounts of data, this method often requires extensive management and statistical skills on the part of the researcher. Indeed, EMA data are often analyzed using multilevel modeling procedures that test for patterns within and across participants simultaneously.

EMA is not without its limitations, however. Besides being time- and resource-intensive for both researchers and participants, EMA does not allow full laboratory control over key variables—a condition often necessary to draw causal conclusions. For this reason, EMA is often used as a way to supplement traditional lab-based procedures and gain a more complete picture of a given psychological or physical phenomenon.

Despite methodological and technical challenges, EMA has played an increasingly vital role in the health and behavioral sciences. It has been used to examine questions associated with psychological health, including coping, subjective well-being, and the phenomenology of emotional experience. Evidence

that standard self-report questionnaires can be biased measures of everyday experience bolsters this work. For example, global and retrospective accounts of emotional experiences often reflect people's beliefs or theories about their experiences, and such accounts are often disproportionately influenced by people's current emotional state or by their most salient or recent experiences.

EMA has also been an especially innovative way to examine properties related to physical health (for examples, see Stone, Shiffman, & DeVries, 1999). Applications have included the temporal properties of heart rate or blood pressure and salivary cortisol levels, which, in turn, have provided insight into their effects on cardiovascular disease and stress. EMA also has been used to inform and evaluate the efficacy of clinical interventions and health treatments—a use that is especially relevant in light of evidence questioning the accuracy of people's retrospective accounts of their physical and psychological symptoms. Applications have included assessing interventions to treat respiratory distress, chronic pain, and smoking.

In all, great progress has been made in studies utilizing EMA, garnering strong implications for theory, research, and practice within the physical and psychological health sciences. Given these advances to date, EMA holds much promise as a valuable tool in other research domains.

## ECOSOCIAL THEORY

---

Ecosocial theory is an emerging multilevel *theory of disease distribution* that seeks to integrate social and biologic reasoning, along with a dynamic, historical, and ecological perspective, to address population distributions of disease and social inequalities in health. Guided by the question, Who and what drives current and changing patterns of social inequalities in health?, its central focus is on how people literally embody—biologically—social conditions, thereby generating inequitable population distributions of health. Distinguishing features of ecosocial theory include its emphasis on (a) the importance of explicit theoretical frameworks for epidemiological and other public health research and (b) the accountability of public health scientists and practitioners for the frameworks, questions, and data they do—or do not—employ in their daily work.

From an ecosocial perspective, theory is essential to epidemiological and other public research and practice for three reasons (Krieger, 2001a). First, as in any science, theory is what helps us structure our ideas, serving as mental scaffolding for interrelated sets of ideas whose plausibility can be tested by human action and thought. It is what enables us to explain causal connections between specified phenomena within and across specified domains. Second, theory is critical for public health research and practice, because shared observations of disparities in health do not necessarily translate to common understandings of cause. Consider explanations for long-standing racial/ethnic disparities in health: it is theory, not data, that determines whether racism versus “race” is investigated as causing the observed associations. Third, bringing together social and biological constructs to explain population patterns of health, disease, and well-being requires more than simply generating laundry lists of “social” and “biological” risk factors. Also required are multilevel frameworks and methods for

conceptualizing, operationalizing, analyzing, and interpreting social disparities in health in relation to categories reflecting inequitable social relations, including socioeconomic position, gender, race/ethnicity, and sexuality. Social *and* biologic plausibility matter; neither alone is sufficient for evaluating explanations of distributions of disease, disability, and death (Krieger, 2000). Absent theory to illuminate what is missing and to highlight what is thought to be known, coherent explanations cannot be assembled or tested.

First proposed in 1994 (Krieger, 1994), ecosocial theory has helped galvanize renewed attention to the theoretical foundations of explaining social determinants of health. In contrast to dominant individualistic biomedical and lifestyle explanations of *disease causation*, ecosocial theory is a theory of *disease distribution* that seeks to explain *population distributions of health*. Its four core constructs, elaborated below, are embodiment, pathways of embodiment, cumulative interplay of exposure, susceptibility, and resistance across the lifecourse, and accountability and agency (Krieger, 1994, 2001a). Concerned with literal embodiment of adverse social, physical, and biological exposures from conception to death, this framework is well suited for research on population health in general, and social inequalities in health in particular. This is because ecosocial theory (a) draws attention to the combined impact of societal determinants of health, both social and physical, at multiple levels and scales, and in relation to health outcomes spanning from conception to death, (b) encourages research that promotes understanding of and initiatives to address societal responsibility for social inequalities in health, and (c) explicitly recognizes that scientific knowledge and hypotheses are socially situated, and that insights and experiences of affected communities along with the ideas of researchers, past and present, are germane to fruitful scientific inquiry and public health practice.

To aid conceptualization, ecosocial theory employs a visual fractal metaphor of an evolving bush of life intertwined with the scaffolding of society that different core social groups daily reinforce or seek to alter (Krieger, 1994, 2000, 2001a). This fractal metaphor emphasizes the simultaneity of causation at multiple levels and scales, challenging conventional approaches to parsing out “causes” as “proximal” or “distal.” Rather, by drawing on the imagery of fractals—which are recursive structures, repeating and self-similar at

every scale, from micro to macro—ecosocial theory invites analysis of current and changing population patterns of health, disease, and well-being in relation to *each* level of biological, ecological, and social organization (e.g., cell, organ, organism/individual, family, community, population, society, ecosystem) as manifested at *each* and every scale, whether relatively small and fast (e.g., enzyme catalysis) or relatively large and slow (e.g., infection and renewal of the pool of susceptibles for a specified infectious disease). The ultimate goal is to develop epidemiological explanations that account for both persisting and changing distributions—across time and space—of health, disease, and well-being, including social inequalities in health, and generate knowledge useful for promoting social equity in health.

## ECOSOCIAL THEORY: KEY CONSTRUCTS

Several key constructs are important in ecosocial theory:

- *Embodiment*: a concept referring to how we literally incorporate, biologically, the material and social world in which we live, from in utero to death; a corollary is that no aspect of our biology can be understood absent knowledge of history and individual and societal ways of living.
- *Pathways of embodiment*: structured simultaneously by (a) societal arrangements of power, property, and contingent patterns of production, consumption, and reproduction, and (b) constraints and possibilities of our biology, as shaped by our species’ evolutionary history, our ecologic context, and individual histories—that is, trajectories of biologic and social development.
- *Cumulative interplay between exposure, susceptibility, and resistance*: expressed in pathways of embodiment, with each factor and its distribution conceptualized at multiple levels (individual, neighborhood, regional or political jurisdiction, national, international or supranational) and in multiple domains (e.g., home, work, school, other public settings), in relation to relevant ecologic niches, and manifested in processes at multiple scales of time and space.
- *Accountability and agency*: expressed in pathways of and knowledge about embodiment, in relation to institutions (government, business, and public sector),

communities, households, and individuals, and also to accountability and agency of epidemiologists and other scientists for theories used and ignored to explain social inequalities in health; a corollary is that, given likely complementary causal explanations at different scales and levels, epidemiological studies should explicitly name and consider the benefits and limitations of their particular scale and level of analysis.

## EFFECT MODIFICATION

The term *effect modification* has been applied to two distinct phenomena. Referring to the first phenomenon, effect modification simply means that some chosen measure of effect varies across levels of background variables. This phenomenon is more precisely termed effect-measure modification (Rothman & Greenland, 1998, chap. 4), and in the statistics literature is more often termed *heterogeneity* or “interaction.” Referring to the second phenomenon, effect modification means that the mechanism of effect differs with background variables, which is known in the biomedical literature as *dependent action* or (again) “interaction.” The two phenomena are sometimes

confused, as reflected by the use of the same terms (*effect modification*, *interaction*) for both, but in fact they have only limited points of contact.

To make the concepts and distinctions precise, suppose we are studying the effects that changes in a variable  $X$  will have on a subsequent variable  $Y$ , in the presence of a background variable  $Z$  that precedes  $X$  and  $Y$ . For example,  $X$  might be a treatment level such as dose or treatment arm,  $Y$  might be a health outcome variable such as life expectancy following treatment, and  $Z$  might be sex (1 = female, 0 = male). To measure effects, write  $Y_x$  for the outcome one would have if administered treatment level  $x$  of  $X$ ; for example, if  $X = 1$  for active treatment,  $X = 0$  for placebo, then  $Y_1$  is the outcome a subject will have if  $X = 1$  is administered and  $Y_0$  is the outcome a subject will have if  $X = 0$  is administered. (The  $Y_x$  are often called *potential outcomes*; see Rubin, 1990, for a history of their use in statistics, Greenland & Brumback, 2002, for a basic review of connection to other causal modeling concepts such as structural equations and path diagrams, and Pearl, 2000, for an advanced treatment.)

A common measure of the effect of changing  $X$  from 0 to 1 on the outcome is the difference  $Y_1 - Y_0$ ; for example, if  $Y$  were life expectancy,  $Y_1 - Y_0$  would be the change in life expectancy. If this difference varied with sex in a systematic fashion, one could say that the difference was modified by sex, or that there was heterogeneity of the difference across sex. Another common measure of effect is the ratio  $Y_1/Y_0$ ; if this ratio varied with sex in a systematic fashion, one could say that the ratio was modified by sex.

For purely algebraic reasons, two measures may be modified in very different ways by the same variable. Furthermore, if both  $X$  and  $Z$  affect  $Y$ , absence of modification of the difference implies modification of the ratio, and vice versa. As a simple example, suppose for the subjects under study,  $Y_1 = 20$  and  $Y_0 = 10$  for all the males, but  $Y_1 = 30$  and  $Y_0 = 15$  for all the females. Then  $Y_1 - Y_0 = 10$  for males but  $Y_1 - Y_0 = 15$  for females, so there is 5-year modification of the difference measure by sex. But suppose we measured the effects by expectancy ratios  $Y_1/Y_0$ , instead of differences. Then  $Y_1/Y_0 = 20/10 = 2$  for males and  $Y_1/Y_0 = 30/15 = 2$  for females as well, so there is no modification of the ratio measure by sex. Consider next an example in which  $Y_1 = 20$  and  $Y_0 = 10$  for all the males, and  $Y_1 = 30$  and  $Y_0 = 20$  for all the females. Then  $Y_1 - Y_0 = 10$  for both males and females, so there is no modification of the difference by sex. But  $Y_1/Y_0 = 20/10 = 2$  for males and

$Y_1/Y_0 = 30/20 = 1.5$  for females, so there is modification of the ratio by sex.

Such illustrations show that one should not in general equate the presence or absence of effect-measure modification to the presence or absence of interactions in the biologic (mechanistic) sense, because effect-measure modification depends entirely on what measure one chooses to examine, whereas the mechanism is the same regardless of that choice. Nonetheless, it is possible to formulate mechanisms of action that imply absence of modification (homogeneity) of a particular measure. For such a mechanism, the observation of heterogeneity in that measure can be taken as evidence against the mechanism (assuming, of course, that the observations are valid). A classic example is the simple "independent action" model for the effect of X and Z on Y, in which subjects affected by changes in X are disjoint from subjects affected by changes in Z (e.g., see Weinberg, 1986). This model implies homogeneity (*absence* of modification by Z) of the average X effect when that effect is measured by the difference in Y; if X and Z both have effects, this homogeneity of the difference forces there to be heterogeneity (modification) of the ratio across Z. For further details of this connection, and the relation of effect modification to concepts of synergy and antagonism, see Greenland and Poole (1988), Greenland (1993), and Rothman and Greenland (1998, chaps. 4, 18).

## EFFORT-REWARD IMBALANCE

---

In general, people aim at reaching a reasonable balance between the resources invested in cooperative activities and the gains received in turn. All major contracts in social life are based on the principle of reciprocity. Rooted in human evolution, reciprocal exchange reinforces trust and the quality of social relationships, thus enhancing positive emotions and a sense of well-being. Conversely, violation of reciprocity threatens social stability and the self-esteem of contributing people. Recurrent experience of failed reciprocity elicits strong negative emotions and associated stress responses, which, in the long run, contribute to illness susceptibility and reduced well-being. The model of effort-reward imbalance has been developed (a) to identify conditions of failed reciprocity in social life, (b) to explain their pervasiveness, and (c) to predict adverse health outcomes of exposure to this type of stressful experience (Siegrist, 1996). Therefore, this model provides a sociological contribution to the study of social determinants of human health and disease. As it can be reliably measured, the model has been tested in a number of epidemiological, clinical, and laboratory investigations. Moreover, based on evidence of its ability to explain elevated risks of stress-related diseases, the model may be useful in guiding activities of disease prevention and health promotion.

## THEORETICAL BACKGROUND

The model of effort-reward imbalance is derived from a more general approach toward analyzing the psychosocial dimension of human health and well-being. It assumes that personal self-regulation conducive to health is largely contingent on successful social exchange as mediated through salient roles. The marital and parental roles, the work role, and the different civic roles offer opportunities of conducting reciprocated activities that matter for people's need fulfillment, including a favorable sense of self-esteem and self-efficacy.

In adult life the work role is of crucial importance in this respect for at least three reasons. First, having a job is normally a prerequisite for a regular income. Level of income determines a wide range of life chances. Second, training for a job and achievement of occupational status are the most important goals of primary and secondary socialization. It is through education, job training, and status acquisition that personal growth and development are realized, that a core social identity outside the family is acquired, and that goal-directed activity in human life is shaped. Third, occupation defines a most important criterion of social stratification in advanced societies. Amount of esteem and social approval in interpersonal life largely depend on the type of job, professional training, and level of occupational achievement. Alternatively, losing a job and being excluded from the labor market are obvious examples of role termination with deleterious effects on self-regulation, on emotional well-being and health. While termination of the work role by exclusion or loss may define the most visible and stressful experience related to occupational life, other constellations of unfavorable social exchange through the work role are often more prevalent and, perhaps, equally stressful. One such constellation has been identified as the lack of reciprocity between efforts spent and rewards received at work. In view of the centrality of work and occupation in adult life, intense and long-lasting effects on disturbed self-regulation, and particularly self-esteem, are expected to occur in this context. For these reasons the model of effort-reward imbalance has been studied primarily with reference to the work role, and most evidence is available in this context. However, more recently, extensions toward measuring nonreciprocal exchange in other core social roles have been developed.

As mentioned, effort at work is spent as a part of a socially organized exchange process to which society at large contributes in terms of rewards. Rewards are distributed by three transmitter systems as scarce resources: money, esteem, and career opportunities. The model of effort-reward imbalance claims that lack of reciprocity between the costs and gains (i.e., high cost/low gain conditions) elicits negative emotions with special propensity to sustained autonomic and neuroendocrine activation. In structural terms, this imbalance results from the fact that the social exchange between employee and employer is based on an incomplete contract that does not specify the full range of detailed obligations and benefits. In

incomplete contracts, assumptions of trust in mutual commitment are made. However, the model defines three conditions that result in recurrent high cost/low gain experience at work. First, the risk of nonreciprocity in exchange is particularly high if employees have no alternative choice in the labor market, if their skills are poor, or if they subscribe to short-term contracts. Second, employees may accept job arrangements that are considered unfair for a certain time for strategic reasons as they tend to improve their chances for career promotion and related rewards at a later stage. This pattern is often observed in early stages of professional careers. Failed success after long-lasting investment is particularly harmful to a person's self-regulation. Third, there are psychological reasons of a continued mismatch between efforts and rewards at work. People characterized by a motivational pattern of excessive work-related overcommitment and a high need for approval may suffer from inappropriate perceptions of demands and their own coping resources more often than their less involved colleagues. Perceptual distortion prevents them from accurately assessing cost-gain relations.

The predictions derived from the model are as follows: First, the components of effort and reward each may contribute to reduced health, but the imbalance between high effort and low reward (nonreciprocity) produces adverse effects on health over and above the effects of single components. It is the mismatch between high cost and low gain that matters most (structural component of the model). Second, a high level of personal commitment (overcommitment) acts as an intrinsic trigger of nonreciprocal exchange through the work role and thus adversely affects health (personal component of the model). Third, if structural and personal components act in concert, the strongest effects on health and well-being are expected to occur.

## CONCEPTUAL DIFFERENCES

It is important to emphasize conceptual differences between this theoretical model and related conceptual approaches toward studying psychosocial stress at work, such as control theory (in particular the demand-control model [Karasek & Theorell, 1990]) and equity theory (Adams, 1963). The demand-control model has been introduced to assess specific features of job task profiles that restrict decision making and learning opportunities. This model does

not include personal coping characteristics, nor does it address more distant labor market conditions, such as career opportunities, forced mobility, earnings, or job security, as is the case with the model of effort-reward imbalance at work. In view of the documented effects on health produced by high demand/low control jobs and by jobs defined by effort-reward imbalance, the study of combined effects of these two complementary models seems promising. Equity theory derived from social psychology posits that any deviation from an expected balance between inputs and outcomes has negative consequences and that judgments on this balance rely on processes of social comparison with a reference group. According to equity theory, receiving too much is considered as detrimental as receiving too little. This proposition clearly differs from the model of effort-reward imbalance where inappropriately low gain only matters for adverse outcomes. This conclusion is in accordance with evidence derived from neuroscience research showing that affective responses are faster and stronger to proximate negative events than to positive ones. A further substantial difference between equity theory and the model of effort-reward imbalance concerns the latter's foundation in sociological role theory.

### Measurements

The measurement of the model of effort-reward imbalance at work is largely restricted to self-report data, first, because it combines descriptive and evaluative information on perceived demands (effort) and rewards and, second, because it requires information on personal coping characteristics (overcommitment). Moreover, information on more distant working conditions can hardly be collected by objective measures. Thus, assessment of effort-reward imbalance at work relies on indicators that are measured by psychometric scales containing Likert-scaled items. Essentially, three psychometric scales are measured (effort, reward, overcommitment), and the combination of information from these scales, according to a predefined algorithm, provides an opportunity of measuring the underlying construct. In its most economic version, the standardized questionnaire contains 23 items, with 6 items measuring effort, 11 items measuring rewards, and 6 items measuring overcommitment (short version). The unidimensionality of each scale has been confirmed in several studies, and acceptable internal consistency ranging from about

0.70 to about 0.90 was found. To test the main assumption, a ratio of the sum score of the effort scale and of the sum score of the reward scale is computed, adjusting for different numbers of items in the numerator and denominator. The construction of this ratio serves as an approximate estimate of the imbalance between costs and gains experienced in everyday working life. Scoring high on this ratio (e.g., belonging to the upper quartile of the score distribution) is expected to predict an increased risk of disease. Scoring high on the scale overcommitment is also expected to increase the risk of illness, but especially so in combination with the ratio. Additional ways of measuring the imbalance between effort and reward have been suggested, and alternative ways of modeling associations of these variables with health outcomes are being explored, but the ones summarized here reflect agreed-upon and widely used procedures.

### Importance for Health

Prospective observational studies of large cohorts of initially healthy men and women are considered a gold standard for testing a possible causal role of psychosocial conditions, such as effort-reward imbalance, in health and disease. In addition, experimental evidence and information derived from intervention studies are crucial. Valuable, although methodologically less convincing data are derived from case-control studies and from cross-sectional epidemiological investigations. At least 4 prospective and 2 semi-prospective studies, some 20 cross-sectional or case-control studies, and 2 experimental and 2 intervention studies, have tested the model so far. In many investigations, coronary heart disease or established cardiovascular risk factors, such as hypertension, elevated blood lipids, high level of fibrinogen, cigarette smoking, and alcohol dependence, were analyzed using multivariate logistic regression analysis.

In general, the relative risk (or odds ratio) of suffering from one of these health conditions is increased by 50% to 150% in men and women characterized by effort-reward imbalance, compared to those who are free from this type of stress at work. One line of evidence on these associations comes from the well-known Whitehall II study in the United Kingdom where 10,308 men and women were followed over a mean 5.3 years. As the original questionnaire measuring effort-reward imbalance was not part of the initial screening, but was

included at a later stage, proxy measures were derived for risk estimation. After 5 years, men and women suffering from effort-reward imbalance at work had a 2.2-fold increased risk of exhibiting coronary heart disease compared to nonstressed employees. This result was obtained after controlling for a large number of potentially confounding factors (Marmot, Theorell, & Siegrist, 2002). Most recent information indicates that this association, although attenuated, still persisted 11 years after initial screening. The Whitehall II study is especially important because it documents associations of effort-reward imbalance with additional health measures, in particular, mild-to-moderate psychiatric disorders, alcohol dependence, and reduced physical, mental, and social functioning. Interestingly, adverse effects on health produced by nonreciprocal exchange at work were also found in studies in China and Japan, indicating that the validity of the model is not restricted to Western societies.

A different line of evidence concerns laboratory studies exploring psychobiologic pathways that may underlie the association of occupational stress with bodily dysfunction and disease. In a Dutch study, ambulatory blood pressure and heart rate monitoring on 3 days of a work week was conducted in male employees of a computer company. The group with high scores of the effort/reward ratio exhibited significantly higher mean systolic blood pressure and heart rate values compared to the group without occupational stress. Moreover, mean heart rate variability was lower among stressed employees (Vrijkotte, van Doornen, & de Geus, 2000). Poor self-rated health is considered a meaningful indicator of ill health, as it has been associated with an elevated risk of mortality in many studies. Prospective and cross-sectional evidence is now available indicating a higher probability of poor self-rated health in women and men defined by effort-reward imbalance at work. These associations were found to be particularly strong in populations living in Central and Eastern Europe, a region that has recently witnessed profound socioeconomic threats and changes. Although the construct of effort-reward imbalance has been used as a variable predicting health outcomes, it may also be considered a dependent variable in studies dealing with differences or changes in work organization or in studies comparing organizational justice.

## Importance for Aging

The relevance of nonreciprocal exchange is not restricted to the working life. The work/nonwork interface is important, as negative spillover from work to family life and vice versa may aggravate stressful experience and its adverse consequences for health. Alternatively, favorable conditions outside work can buffer stress reactions that were generated in occupational life. The importance of the model of effort-reward imbalance for aging is illustrated at two levels. First, a cumulation of social reward deficiency experienced in different important roles in midlife is expected to accelerate aging processes in the organism along with an increased illness susceptibility. This is best explained by the free radical theory of aging. Under conditions of chronic psychosocial stress, metabolism in the body is increased. As a consequence, the production of free radicals is enhanced that damage lipids, proteins, and the DNA. Enhanced endogenous oxidation is a major contributor to accelerated aging and degenerative diseases associated with aging.

At a second level, the balance between effort and reward may be important in promoting health and well-being in early old age. Early old age defines a life stage (ranging from about 60 to about 80 years) where opportunities of social productivity and of successful material and psychological need fulfillment through social exchange are limited. This is the case despite the fact that a high proportion of people living in their early old age function well and are indeed motivated to contribute and to perform. Society at large has not yet responded to the challenge of providing a variety of social roles to this growing proportion of the population. It is concluded from this theoretical framework that healthy aging in early old age is greatly enhanced if people are offered social roles that enable them to continue their favorable experience of self-efficacy, self-esteem, and belonging. It is through continued exposure to a controllable challenge and to positive feedback from significant others to one's achievement that a sense of mastery, of worth, and of meaning is reinforced, and that one's motivation and energy are mobilized. These social roles in early old age may include work arrangements beyond traditional retirement age and new forms of social productivity, such as voluntary work, honorary offices, or membership in civic associations and networks.

## Intervention and Policy Implications

The model of effort-reward imbalance at work is useful in designing work site stress prevention and health promotion programs. As a first step, stressful conditions at work can be measured in a standardized way, using psychometrically validated questionnaires that are available in a number of languages. Therefore, the amount of work stress can be assessed for different occupational groups, departments, or organizations. As a second step, intervention measures can be derived from the model at the personal/interpersonal level and at the structural level. At the personal/interpersonal level, techniques of stress management, including stress inoculation through strengthening of psychological and interpersonal resources, are indicated. In order to be effective, these techniques need to address cognitions, attitudes, and job-related motivations in addition to the rather nonspecific relaxation techniques. In one such interventional approach that was conducted in a group of highly stressed inner-city bus drivers, expert-guided group work addressed the coping pattern of work-related overcommitment. After twelve 2-hour sessions, a highly significant decrease in mean level of overcommitment was observed in the intervention group compared to a control group, and this effect remained stable over a 3-month follow-up period. Improved self-observation and perception of arousal, coping with anger, and reinforced self-reliance were important elements of this intervention (Dunham, 2001). Another application of stress prevention at the interpersonal level concerns the improvement of leadership skills among supervisors and superiors, in particular the awareness of an important role of esteem, recognition, and appropriate feedback, as indicated by the model of effort-reward imbalance. Structural measures of work site health promotion derived from the model include the implementation of models of gain-sharing and of nonmonetary incentives, including options of flexible work time arrangements, comparatively high compensation contingent on performance, tailoring of promotion prospects and status according to achievements, improved job security, and further measures of organizational justice.

Obviously, opportunities for structural measures are limited under the constraints of economic globalization. Moreover, technological progress and changes in the labor market reduce the options of organization-based stress prevention. Extension of homework and virtual organizations and a growing proportion of

self-employed people, freelancers, and small teams are examples of these developments. In addition, short-term or part-time contracts and high turnover rates within organizations, rapid technological changes, and instability in the face of merging and downsizing of companies aggravate the situation. Yet, as an important study from the Harvard Business School documented, distinct structural measures aiming at the creation of healthy workplaces (in terms of models such as demand-control and effort-reward imbalance) produce economic benefits as well. These measures include employment security, selective hiring of new personnel, decentralization of decision making, adequate compensation, and extensive training of employees, among others (Pfeffer, 1998). Policy implications of the model of effort-reward imbalance are not restricted to occupational life, but may be extended to the design of voluntary work and to ways of improving social capital within communities.

In summary, effort-reward imbalance in core social roles in adult life is now considered a significant risk factor for the development of stress-related diseases and ill health, in particular coronary heart disease, depression, some forms of addiction, and poor self-rated health. Current evidence indicates that adverse effects on health are prevalent among men and women in midlife and early old life, and that these effects are not restricted to modern Western societies. The ubiquity and intensity of stressful experience elicited by failed reciprocity points to the evolutionary significance of this norm of social exchange. It will be an important scientific task to explore the pathways leading from conditions of social reward deficiency to stress-related diseases, with a particular focus on the brain's reward system (Siegrist, 2000). A different future task concerns the extension of intervention studies that examine the potentially beneficial effects of reducing the imbalance between effort and reward in social roles, most importantly in the work role. So far, this model evolving from interdisciplinary research in medical sociology has documented its scientific value. It remains to be seen how far this new scientific evidence can be transferred into health-promoting policy measures that diminish the burden of societal stress.

## EMOTIONS: NEGATIVE EMOTIONS AND HEALTH

From Greek and Roman antiquity to modern times, the belief that emotions affect physical health has pervaded popular culture and scientific theory. Recent technological advances have helped elucidate the physiological correlates of negative emotions, and, in combination with a growing body of epidemiological research, suggest that the role of negative emotions in health is more than medical folklore. The current entry provides an overview of the research relating negative emotions to health, focusing on the broadly defined constructs of depression, anxiety, and anger. The content focuses on the influence of negative emotions in the development and course of disease, as opposed to the reverse pathway from disease to emotion, although in reality the relationship is no doubt bidirectional. The entry begins by providing a brief historical perspective on the function of emotions in health, followed by a discussion of definitions and

conceptualization of terms in emotion research. An overview of possible mechanisms underlying the association of negative emotions with health is then provided. Findings from research connecting negative emotions with the etiology and course of chronic and acute disease processes are then summarized. The entry concludes with a discussion of future directions, focusing on factors that may help explain the circumstances under which negative emotions are most likely to impact health.

## HISTORICAL PERSPECTIVE

The belief that emotions can affect health has had a principal influence on medicine for centuries. As the field of medicine emerged, Hippocrates (ca. 460–ca. 370 B.C.) and his successors proposed the existence of four distinct “humors” (black bile, yellow bile, phlegm, and blood). Humors were viewed as direct causes of temperament and emotions, and their imbalance was believed to foster disease. Centuries later, this ideology was expanded by the Greek physician Galen (A.D. 131-201), who proposed that strong emotions represented direct and specific causes of disease, which must be kept in equilibrium to sustain mental and physical health.

The specificity ideology (i.e., the tenet that specific emotions foster specific disease processes) remained a dominant perspective through the inception of psychosomatic medicine in the 1930s, as illustrated in the work of Flandaers Dunbar and Franz Alexander. In an attempt to integrate then current models of psychodynamic psychopathology and physiology, these researchers proposed that unresolved psychic wishes and desires created emotional conflicts, associated physiological responses, and subsequently, diseases in related body systems. For example, repression of aggressive affect and resultant anxiety were believed to underlie essential hypertension. The impact of this theoretical perspective was limited, due to important methodological flaws characteristic of the work. Thus, as psychology moved away from psychodynamic schools of thought, models of emotion and health began to emphasize conscious processes and objective circumstances. At the same time, key advances concerning the physiological stress response were contributed by researchers such as Walter Cannon, and later, Hans Seyle. Seyle’s many texts and articles, in particular, had a marked influence on the growing field of psychosomatic medicine and on

popular culture in the mid-20th century. These developments harkened the abandonment of the specificity model and heralded the modern focus on the roles of stress, emotions, and related processes in verifiable health outcomes.

Until recently, science has lacked the technology to support or refute the centuries-old belief that emotions influence health and disease. However, the past decades have seen striking accomplishments in laboratory technologies, in combination with findings from a number of large-scale, methodologically rigorous studies relating emotions to morbidity (i.e., illness and disability) and mortality (i.e., death) in community and clinical populations. Mounting evidence now suggests that negative emotions have a significant influence on health, and that this association proceeds through a number of behavioral and physiological pathways.

## DEFINITIONS AND DISTINCTIONS IN EMOTION RESEARCH

What is meant by the term *emotion*? Conceptualizations articulated in the scientific literature have varied widely, but emotions are generally thought to comprise subjective feelings, reflecting appraisals (i.e., cognition) regarding a stimulus, and accompanied by behavioral impulses and neurobiological alterations that prepare the body for action. Hence, emotions encompass closely related affective, cognitive, behavioral, and physiological processes.

Most theoretical perspectives also share the notion that all emotions, whether “positive” or “negative,” are adaptive inasmuch as they serve a communicative function. Emotions signal a homeostatic imbalance, or need, to the individual, and they also provide information to others in the social environment. Hence, fear signals a threat and encourages actions that would allow elusion of danger. Anger provides an indication to others that the displayer may behave in an aggressive manner. Notwithstanding their intrinsic adaptive value, emotions have the potential to become harmful when they are inappropriate to the situation, or excessive in frequency, strength, and duration.

Although they are often used interchangeably, a distinction should be formed between the terms *emotion* and *mood*. Most generally, emotions describe brief, intense affective experiences that typically have identifiable targets or precipitants, whereas moods

tend to be more enduring, less intense, and less specific in derivation. On the other hand, moods and emotions are typically closely and jointly related. For example, an individual who is in a depressed mood may have a relatively low threshold for experiencing sadness; likewise, experiences that stimulate sadness may precipitate a long-lasting depressed mood. A further distinction can be made between trait affect (i.e., emotions or moods) and state affect. State affects refer to discrete emotional experiences, whereas trait affects reflect the dispositional tendency to experience particular emotions or moods across situations and time. These differences are important, because a basic understanding of physiology suggests that emotions must be enduring or repetitive in nature to contribute to the development and progression of chronic diseases. On the other hand, intense bursts of negative affect could trigger acute health events in individuals with underlying disease.

Finally, some researchers assert that emotions can be distinguished according to the underlying dimensions of valence (i.e., whether they are positive or negative) and arousal (i.e., whether they reflect high or low engagement and attention). Emotions that are similar in terms of valence or arousal often cluster, or co-occur. This entry focuses specifically on emotions of negative valence, and varying levels of arousal, which have been examined with some methodological rigor and frequency in relation to verifiable health outcomes, namely depression, anxiety, and anger. (For a discussion of positive emotions and health, see Emotions: Positive Emotions and Health, this volume.)

## How Might Negative Emotions Affect Health?

Recent scientific achievements have hastened substantial changes from the specificity approach to the current understanding of the roles of emotions in health. Contemporary perspectives acknowledge that many emotions may affect diverse health outcomes, and that the connection from emotions to disease is likely to proceed through multiple pathways. The influence of negative emotions may occur indirectly, through health behaviors or nonadherence to proscribed medical regimens, and it may also proceed directly through physiological pathways. In respect to the latter, recent research has begun to elucidate the physiological correlates of emotions, which appear to involve alterations in cardiovascular, neuroendocrine, and immune system functioning.

### *Indirect Pathways*

As reviewed by Kiecolt-Glaser, McGuire, Robles, and Glaser (2002) and Tracy Mayne (1999), research has shown that distressed individuals tend to engage in unhealthy behaviors such as smoking, leading a sedentary lifestyle, eating poorly, obtaining limited or disturbed sleep, and using alcohol and drugs. These habits are often interrelated (e.g., use of alcohol and drugs typically abets disturbed sleep), and they may lead to further emotional disturbances, creating cyclic and repetitive influences on health. Additional research suggests that once illness occurs, emotionally distressed individuals are less likely to adhere to lifestyle changes and medication regimens prescribed by health care providers, relative to their nondistressed counterparts. Thus, behavioral pathways may contribute to the association between negative emotions and outcomes in clinically ill populations. In part, this association may reflect the fact that individuals with higher levels of negative emotions tend to report lower levels of control, or “self-efficacy,” over their health and environments. Having a strong sense of self-efficacy has been shown to be strongly predictive of engaging in health-promoting behaviors and avoiding health-damaging behaviors. Moreover, negative health practices such as smoking or consumption of substances may represent maladaptive attempts to cope with, or manage, feelings of distress.

### *Direct Pathways*

Studies that have examined health practices suggest that they do not account completely for associations between negative emotions and health. Consistently, research suggests that negative emotions engender physiological changes that, in turn, have been shown to predict worse health outcomes. As alluded to previously, emotions are typically accompanied by behavioral impulses—that is, to fight or flee in the case of anxiety and anger, and to withdraw from the environment and conserve energy when experiencing depression. Physiological alterations occur that would facilitate enactment of these behaviors, which can be viewed as adaptive in this regard. However, emotional activation that is incongruent with environmental demands (i.e., when emotion is inappropriate or excessive in intensity, duration, or frequency) may overtax the system, leading to disease vulnerability.

As summarized in detailed reviews by Kiecolt-Glaser and colleagues (2002) and Mayne (1999),

negative emotions have been linked to hyperactivity of the sympathetic-adrenal medullary (SAM) system and alterations in the hypothalamic-pituitary-adrenocortical (HPA) axis. Activation of these systems prompts the release of stress hormones (e.g., catecholamines, cortisol) and promotes increases in cardiovascular responses (e.g., blood pressure, heart rate). When enacted repetitively over time, these alterations are believed to contribute to the etiology and course of cardiovascular diseases (CVD) by hastening atherosclerosis (i.e., the buildup of fats and other substances in the arteries, which underlies the clinical manifestations of heart disease) and increasing vulnerability to clinical events in patients with atherosclerosis. Additional evidence suggests that negative emotions and attitudes affect immune functioning and, through this pathway, might relate to additional outcomes, such as infectious diseases, autoimmune disorders, cancer, and atherosclerosis. Most important, current understanding of the roles of these physiological alternations in illness—and of the nature of the effects of negative emotions on these processes—is incomplete; further research is clearly warranted. Nonetheless, growing evidence suggests that the link between negative emotions and health proceeds, at least in part, through physiological channels.

As implied by the above discussion, the degree to which negative emotions display similar or distinct physiological correlates is currently unclear. Negative emotions often occur concomitantly, creating difficulty in isolating their discrete effects. However, as noted by Kubzansky and Kawachi (2000), effects may differ due to the nature of behavioral coping processes associated with different negative emotions. For example, anxiety encourages active efforts to escape fear-provoking stimuli, whereas depression tends to be characterized by passive behavioral and psychological withdrawal. As a result, the physiological processes associated with these emotional experiences may vary, as may their ultimate health effects. Further research is needed to explore these issues more carefully.

### **Negative Emotions, Morbidity, and Mortality**

Progress in understanding the health correlates of negative emotions can be attributed to some extent to methodologically rigorous studies that have examined the association of these constructs with objective indicators of morbidity (i.e., cases of heart disease, cancer, and other diseases) and mortality (i.e., rates of

death). The next sections highlight some of the central evidence that has related depression, anxiety, and anger to these endpoints. We focus on these negative emotions in particular, because they have been examined with some regularity and thoroughness in relation to objective health outcomes, and because they have been shown to impact the behavioral and physiological pathways outlined above.

### *Depression, Morbidity, and Mortality*

Depression reflects a combination of negative affects such as sadness, loneliness, and guilt, typically accompanied by negative cognition about the self, world, and future, and often associated with behavioral apathy (i.e., a lack of motivation and interest). Hence, depression is characterized by negative valence and low arousal or engagement in the two-dimensional model of emotion. Depressive disorders consist of a constellation of emotional and behavioral symptoms that pervade situations and persist across time. A study by the World Health Organization suggests that depression is second after CVD as a cause of worldwide disease burden, and that it is the leading cause of worldwide disability. Illustrating the significance of the problem, research sponsored by the National Institute of Mental Health (i.e., the Epidemiologic Catchment Area Study) indicated that in any given year, nearly 19 million U.S. adults have a depressive disorder. Depression is particularly common in individuals experiencing chronic or acute medical problems, and therefore, depression has substantial potential to influence initial disease states as well as their progression and course.

Research concerning depression and health has most frequently incorporated cardiovascular endpoints. Alexander Glassman and Peter Shapiro (1998) evaluated findings from a series of studies that examined depression and the risk of mortality from cardiovascular causes in initially healthy community samples, or in clinically ill samples. Across these studies, the risk of cardiovascular mortality was about 1.5 to 2.0 times higher for depressed than for nondepressed individuals. The effect of depression on mortality risk in patients who were already diagnosed with coronary heart disease (CHD; a subtype of CVD that manifests clinically as angina, i.e., chest pain, heart attack, or sudden cardiac death) was even stronger and more consistent. Specifically, when compared with nondepressed patients, depressed patients

recovering from a cardiac event were about four times as likely to die of CHD.

The research concerning depression and cancer is more limited than that regarding CHD, but a recent well-designed study by Brenda Penninx and her colleagues (1998) suggests that depression may predict the risk of cancer incidence (i.e., new cases). Elderly men and women who did not have cancer at the start of the study and who reported chronic depression (i.e., elevated depressive symptoms for 6 years before the follow-up) were nearly twice as likely to contract cancer as those who were not depressed. This effect applied to diverse cancers and was not explained by other risk factors, such as smoking. In contrast, further studies have found no evidence for an association between depression and cancer, as summarized by Kiecolt-Glaser and her colleagues (2002). Depression has been linked to the development of, and outcomes for, an array of additional health problems, including diabetes, osteoporosis, and chronic obstructive pulmonary disease. Depression and related emotional symptoms have also been shown to hasten immunological deterioration and death in some studies of HIV patients, although contradictory evidence has been reported.

Finally, in addition to affecting diverse specific health risks and outcomes, depression may increase the risk of mortality from all causes. For example, a recent, excellent study performed by Richard Schulz and his colleagues (2000) found that depression was an independent predictor (i.e., distinct from other risk factors such as age, socioeconomic status, health behaviors, and initial health status) of mortality in older adults. However, a review of studies concerning depression and mortality conducted by Wulsin, Vaillant, and Wells (1999) describes considerable conflicting evidence. In aggregate, despite the existence of contradictory findings, research indicates that depression confers important health risks, with the strongest available support for a connection between depression and cardiovascular morbidity and mortality.

### *Anxiety, Morbidity, and Mortality*

Anxiety represents a reaction to a perceived or real threat, characterized by worry, fear, or apprehension about the environment and the future, and often accompanied by actions that promote escape from, or avoidance of, the threat. Like depression, anxiety is characterized by negative valence, but it reflects high

arousal or engagement with the environment. Anxiety symptoms and disorders are common in the population. For example, a large study of mental disorders in the United States (i.e., the National Comorbidity Study) estimated lifetime and 12-month prevalence rates for all anxiety disorders at approximately 25% and 17% respectively.

Despite its prevalence in the population, anxiety has been studied less frequently than depression in relation to objective health outcomes. The research that has been conducted has focused nearly exclusively on cardiovascular morbidity and mortality; only a few studies have examined the association between anxiety and other health endpoints, such as cancer or all-cause mortality, and they provide mixed or very limited evidence that anxiety predicts these health outcomes. Thus, the current section focuses on the more compelling research connecting anxiety with CVD.

Laura Kubzansky and her colleagues (1998, 2000) have published two comprehensive reviews of the literature concerning the association between anxiety and CHD risks and outcomes. They note that several earlier studies concerning small samples of psychiatric patients failed to identify an effect of anxiety on these endpoints. However, these studies were characterized by a number of methodological limitations that prohibit definitive conclusions. More recently, a number of well-designed studies of community dwelling populations suggest that higher levels of anxiety engender an elevated risk for cardiovascular morbidity and mortality. For example, a study from the Normative Aging Study found that initially healthy men who reported anxiety symptoms experienced a higher risk of CHD mortality than for nonanxious men, even after diverse risk factors were accounted for. Risk for sudden cardiac death (i.e., unexpected death due to CHD, occurring shortly after the onset of any cardiac symptoms) was 4.5 times as high for anxious men relative to nonanxious men (see Kawachi, Sparrow, Spiro, Vokonas, & Weiss, 1996, for further details). A review by Rozanski, Blumenthal, and Kaplan (1999) describes additional research indicating that anxiety increases the risks for negative outcomes in patients with underlying CHD. Across studies, patients who were high in anxiety had between 2.5 and 4.9 times the likelihood of negative outcomes, including recurrent events and death from cardiovascular causes, when compared with low-anxious persons. Hence, anxiety appears to confer increased risks for CHD morbidity and mortality, although

further research—especially involving women and ethnically diverse samples—is necessary.

### *Anger, Morbidity, and Mortality*

Anger, which varies widely in intensity from irritation and annoyance to fury or rage, often results from perceptions that one has been treated unfairly, and is typically accompanied by tendencies toward aggressive behavior. Anger is characterized by negative valence and moderate-to-high arousal. Hostility is a closely related construct that refers to a collection of negative beliefs (i.e., cognition) about others. Individuals who are higher in trait hostility tend to be cynical and suspicious of others, and they often experience bitterness and resentment. Anger, hostility, and aggression are conceptually distinct but closely related constructs. Substantial research has examined the health implications of trait hostility, as described in an excellent review performed by Todd Miller and his colleagues (1996). Here we focus explicitly on the research concerning angry emotion and health. Like that regarding anxiety, this research has concerned cardiovascular outcomes nearly exclusively.

As reviewed by Kubzansky and Kawachi (2000), prior research suggests that anger relates to initial CHD, and some data also indicate that higher levels of angry emotion may trigger cardiac events in patient populations. For example, a study of community-dwelling men, performed by Kawachi and colleagues (1996), found that men who scored higher on a measure of trait anger had more than 2.5 times the risk of experiencing a cardiac event across 7 years of follow-up when compared with men who achieved lower anger scores. Findings from the Atherosclerosis Risk in Communities Study—a large study of male and female U.S. residents—identified an association between trait anger and incident stroke and CHD, particularly in subgroups that were otherwise at relatively low risk (for additional information, see Williams et al., 2000; Williams, Nieto, Sanford, Couper, & Tyroler, 2002). Other studies have revealed that anger or habitual ways of expressing anger predict atherosclerosis, and retrospective studies indicate that heart attacks may be more likely to occur following intense anger episodes. Thus, at least preliminary research suggests that anger relates to the etiology and course of cardiovascular diseases, and particularly CHD (for further discussion, also see Rozanski et al., 1999; Kubzansky & Kawachi, 2000; Miller et al., 1996).

## CONCLUDING COMMENTS AND FUTURE RESEARCH DIRECTIONS

A substantial body of research suggests that negative emotions, including depression, anxiety, and anger, confer an increased risk for adverse health outcomes, particularly cardiovascular morbidity and mortality. Advances in scientific technologies for studying the physiological underpinnings of emotions and disease processes have helped explicate the pathways through which these health effects occur. Nonetheless, numerous unresolved questions indicate the need for further research.

For example, the pattern of physiological alterations associated with negative emotions suggests that these constructs probably impact health outcomes other than those related to CVD. Some preliminary evidence is consistent with this assertion, but further research is needed to explore alternative endpoints more thoroughly. Additional research that includes refined conceptualizations and measurements of emotions at both normal and clinically significant levels is also needed to determine the threshold at which negative health outcomes occur, and to determine if discrete negative emotions have distinct, additive, and/or synergistic (i.e., multiplicative) effects when present in combination. Substantial overlap among constructs and the tendency for negative emotions to co-occur make explicating the health implications of specific emotions a difficult endeavor. Yet, research that attempts to accomplish this goal will be critical for prevention and intervention efforts.

Future research is also needed to explore the individual and environmental circumstances under which negative emotions are most likely to have a detrimental impact on health. Kiecolt-Glaser et al. (2002) describe a number of factors that may influence “vulnerability” and “resiliency” to the health effects of negative emotions. They note that age is likely to be a moderating factor, so that associations may be strongest during both early and late developmental stages (i.e., childhood and older age). Future research should therefore adopt a developmental perspective to explore if different phases in the lifespan represent critical periods for the effects of emotions on health. Gender may also have an important moderating function. For example, women experience the negative emotions of depression and anxiety far more frequently than men, whereas men report higher levels of anger and hostility. Hence, different emotional processes might be of greater consequence for men’s

versus women’s health. Ethnic/racial differences in levels of negative emotions are less clear. However, due to the potential for increased stress created by exposure to racism and discrimination, and a greater likelihood of residing in low socioeconomic status (SES) environments, minority ethnicity could conceivably increase one’s vulnerability to the health implications of negative emotions. Perhaps these and related psychosocial experiences contribute to the substantial health disparities observed across ethnic groupings.

Additional research suggests the importance of considering SES (i.e., educational attainment, income, occupation status, or community indicators of affluence) in studies of emotion and health. For example, a recent paper by Linda Gallo and Karen Matthews (2003) reviews research suggesting that negative emotional states and disorders are more likely to occur in individuals with lower personal or contextual SES. Furthermore, they describe the importance of a “reserve capacity” of resources (e.g., supportive relationships, self-efficacy) that could protect against the development of negative emotions. The reverse capacity may be less developed in persons with lower SES due to the greater environmental demands they experience, thereby contributing to their vulnerability to negative emotions. Relatedly, although the current entry assumes an individual perspective, environmental contexts are likely to have an important function in shaping emotional states and traits, and should be afforded additional attention. Hence, future research concerning emotions and health must strive to incorporate diverse samples, followed over time and through different developmental stages, to collect information concerning potential vulnerability or resiliency variables (e.g., SES, gender, ethnicity, reserve capacity resources, social networks and experiences, personality), and to examine how environmental contexts may foster or protect against negative emotions and their subsequent health effects.

Despite the many remaining unresolved questions, substantial progress has occurred in understanding the effects of emotions on health since the times of Hippocrates. Future years will undoubtedly continue to see emotions take a more central position in efforts to understand, prevent, and intervene in health and disease processes.

## EMOTIONS: POSITIVE EMOTIONS AND HEALTH

---

Folk theories throughout time have promoted the idea that positive emotions are good for your health. This belief dates back at least to biblical times. Proverbs 17:22 advises that "a cheerful heart is a good medicine." Years later, Norman Cousins's (1979) chronicle of his battle with a serious collagen illness using humor and laughter rekindled popular interest in this idea. Until recently, however, such widespread sentiments remained as anecdotal wisdom, without a structured theory to explain how or why positive emotions may be useful to health. Given psychology's penchant to identify, address, and solve problems, research to date has focused primarily on negative emotions. We argue, however, that positive emotions, though relatively mild in nature, are just as noteworthy. In this entry, we discuss Fredrickson's *broaden-and-build theory* (1998, 2001) to demonstrate that positive emotions may provide a useful antidote to the problems associated with negative emotions. Before we introduce the broaden-and-build theory, we briefly review the literature and demonstrate empirical foundations for the benefits of positive emotions in health.

### PHYSICAL AND PSYCHOLOGICAL HEALTH BENEFITS ASSOCIATED WITH POSITIVE EMOTIONS

Researchers have documented numerous salubrious physical and psychological effects associated with positive emotional states. For example, individuals with greater tendencies to use humor to cope (Halley, 1991; Lefcourt, Davidson-Katz, & Kueneman, 1990;

Lefcourt & Thomas, 1998; Stuber, 2002) and who report daily positive mood (Stone et al., 1987; Stone, Neale, Cox, & Napoli, 1994; Stone, Shiffman, & DeVries, 1999) have stronger immune system defenses. In addition, people who are able to regain and maintain positive emotional states are less likely to get sick or to use medical services when faced with a stressful life experience (Catanzaro & Greenwood, 1994; Goldman, Kraemer, & Salovey, 1996). The tendencies to maintain positive emotions, a positive sense of self, and optimistic (even unrealistically optimistic) beliefs of the future act as resources to buffer against the advancement of disease and death (Aspinwall & Taylor, 1997; Taylor, 1983; Taylor & Brown, 1988; Taylor, Kemeny, Reed, Bower & Gruenewald, 2000).

Interventions that promote positive emotions also produce beneficial consequences to health. Pennebaker and his colleagues, for instance, demonstrate that written emotional disclosure can produce significant enhanced health functioning (for a review, see Pennebaker, 1989), especially when positive emotional content is evident in the writings (Pennebaker & Francis, 1996; Pennebaker, Mayne, & Francis, 1997). Corroborating work shows that the advantages associated with positive emotional writing not only provide short-term health benefits, but most important, these benefits can endure for a lifetime. For example, Danner, Snowdon, and Friesen (2001) found that the positive emotional content in the autobiographies of nuns in early adulthood predicted the likelihood of being alive six decades later. Relatedly, Ostir, Markides, Peek, and Goodwin (2001) report that positive emotions in elderly adults protect against physical debility in old age (e.g., less incidents of stroke). In all, these findings exhibit that positive emotions may be valuable tools not only for immediate health concerns but also for establishing long-term beneficial outcomes.

Physical health benefits associated with positive emotions are further established in research on optimism, a dispositional attribute associated with positive emotions. For example, optimists (compared to pessimists) are less likely to suffer from angina and heart attacks (Kubzansky, Sparrow, Vokonas, & Kawachi, 2001) and show better physical recovery immediately after coronary artery bypass surgery and up to 6 months postsurgery (Carver & Scheier, 1998). Taken together, these studies suggest that the relation between physical health and positive dispositional styles (e.g., optimism) may be due in part to the

chronic positive emotional states engendered by the personality style.

In addition to promoting physical health, cultivating positive emotions is associated with psychological health as well (cf. Fredrickson, Maynard, et al., 2000). For instance, coping strategies related to the occurrence and maintenance of positive emotions (e.g., positive reappraisal, problem-focused coping, infusing ordinary events with positive meaning) have been documented as serving to help buffer against stress (Folkman & Moskowitz, 2000; Park & Folkman, 1997; Schaefer & Moos, 1992) and depressed mood (Davis, Nolen-Hoeksema, & Larson, 1998). These strategies help individuals emerge from crises with new coping skills, closer relationships, and a richer appreciation for life, all of which predict increases in psychological well-being.

Empirical support for the prediction that positive emotions are important facilitators of adaptive coping and adjustment to acute and chronic stress is documented in a number of studies (for a review see Folkman & Moskowitz, 2000). For instance, men who were able to find positive meaning when caring for their partners with AIDS were found to cope more effectively with the distress associated with caregiving and bereavement (Folkman, 1997). Similarly, women who found benefits despite hazardous child delivery and prolonged hospitalization postdelivery evidenced greater well-being, which extended to the developmental well-being of their children (Affleck, Tennen, & Rowe, 1991). The occurrence of positive emotions amidst adversity may provide the necessary psychological rest to help buffer against stress, replenish, and restore further coping efforts (Lazarus, Kanner, & Folkman, 1980).

### **The Broaden-and-Build Theory of Positive Emotions**

What functional significance do positive emotions have in promoting favorable consequences of health? A valuable framework from which to understand why and how positive emotions may be useful is Fredrickson's (1998) broaden-and-build theory of positive emotions. Fredrickson (1998, 2001) has argued that, whereas negative emotions heighten people's autonomic activity and narrow their attention to support specific action tendencies (e.g., attack, escape), positive emotions quell autonomic arousal because they broaden people's attention, thinking, and behavioral

repertoires. The broadening effects can be evidenced in the number of thought-action urges related to particular positive emotions: to play and create when experiencing joy, to explore when experiencing interest, to savor and integrate when experiencing contentment, and to combine play, exploration, and savoring when experiencing love (Fredrickson, 1998).

Evidence for cognitive broadening has been illustrated in a program of research conducted by Isen and colleagues. Across several studies, they have shown that induced positive emotions produce patterns of thought that are notably unusual (Isen, Johnson, Mertz, & Robinson, 1985), flexible (Isen & Daubman, 1984), creative (Isen, Daubman, & Nowicki, 1987), integrative (Isen, Rosenzweig, & Young, 1991), open to information (Estrada, Isen, & Young, 1997), and efficient (Isen & Means, 1983; Isen et al., 1991). As well, induced positive emotions increase people's preferences for variety and broaden their arrays of acceptable behavioral options (Kahn & Isen, 1993). These cognitive effects of positive emotions have been linked to increases in brain dopamine levels (Ashby, Isen, & Turken, 1999). In recent work, Fredrickson and Branigan (2002) demonstrate that, relative to neutral states and negative emotions, positive emotions ranging from low activation (contentment/serenity) to high activation (joy/amusement) broaden the scope of people's visual attention as well as their momentary thought-action repertoires (see also Gasper & Clore, 2002).

According to Fredrickson's theory, these broadened mindsets, in turn, have the effect of *building* an individual's physical, intellectual, psychological, and social resources. Positive emotions can momentarily broaden people's modes of thinking, which in turn can improve one's well-being. Over time, and with repeated experiences of positive emotions, a broadened mindset might become habitual. By consequence, then, the often incidental effect of experiencing a positive emotion is an increase in one's personal resources. Most important, the arsenal of personal resources produced by positive emotions can be drawn on in times of need and used to plan for future outcomes, which may be valuable in facilitating healthy behavioral practices (Fredrickson, Maynard, et al., 2000).

### Undoing Effect of Positive Emotions

Evidence for the broadening hypothesis of the broaden-and-build theory (Fredrickson, 1998, 2001)

has clear implications for the strategies that people use to regulate their negative experiences. Negative emotions narrow the momentary thought-action repertoire, producing autonomic nervous system activation, such as increases in heart rate, vasoconstriction, and blood pressure (Fredrickson, Maynard, et al., 2000; Gross, Fredrickson, & Levenson, 1994; Levenson, Ekman, & Friesen, 1990; Ohman, 2000). In contrast, as we have discussed, positive emotions broaden this same repertoire. As such, positive emotions ought to function as efficient antidotes for the lingering effects of negative emotions. In other words, positive emotions might "correct" or "undo" the aftereffects of negative emotions; we call this the undoing hypothesis (Fredrickson & Levenson, 1998; Fredrickson, Mancuso, Branigan, & Tugade, 2000).

We tested the undoing hypothesis by experimentally inducing high-arousal negative emotion (which engenders increases in cardiovascular arousal) and then randomly assigning participants to view emotionally evocative films. We then measured the time elapsed from the start of the randomly assigned film until the cardiovascular reactions induced by the negative emotion returned to baseline levels. In three independent samples, participants in two positive emotion conditions (high activation: joy/amusement, and low activation: contentment/serenity) exhibited faster cardiovascular recovery than those in a neutral control condition, and faster than those in a sadness condition, which exhibited the most protracted recovery (Fredrickson & Levenson, 1998; Fredrickson, Mancuso, et al., 2000).

### Resilience and Positive Emotions

To the extent that positive emotions broaden an individual's array of thoughts and actions, helping to undo the lingering aftereffects of negative emotions, the broaden-and-build theory (Fredrickson, 1998, 2001) proposes that positive emotions should, in turn, help to build personal resources, such as psychological resilience. Theoretical descriptions of psychological resilience indicate that resilient individuals are able to "bounce back" from stressful experiences quickly and efficiently (Carver, 1998; Lazarus, 1993). This theoretical definition suggests that, compared to their less resilient counterparts, resilient individuals would exhibit faster cardiovascular recovery from negative emotional arousal. Together with our work on the undoing hypothesis (Fredrickson & Levenson,

1998; Fredrickson et al., 2000), the broaden-and-build theory suggests that this ability to bounce back to cardiovascular baseline may be fueled by experiences of positive emotion.

In line with previous correlational studies reporting on a link between positive emotionality and psychological resilience (e.g., Block & Kremen, 1996; Klohnen, 1996; Kumpfer, 1999; Masten, Best, & Garmezy, 1990; Werner & Smith, 1992), we predicted that positive emotions contribute to the effects of psychological resilience on effective emotion regulation. We induced negative emotion in participants with a time-pressured speech preparation task. Individuals high in self-reported psychological resilience (Block & Kremen, 1996) reported greater positive emotions in general and in response to the speech preparation task. Moreover, those with higher resilience demonstrated faster cardiovascular recovery from the speech task. Most important, positive emotions at least partially mediated the effect of resilience on cardiovascular recovery. These findings suggest that resilient people may harness positive emotions and use them “intelligently” to achieve their superior coping outcomes (Tugade & Fredrickson, 2002).

### Positive Emotions Build Enduring Resources

To the extent that positive emotions broaden thinking and build enduring psychological resources like resilience, they should also trigger upward spirals toward enhanced emotional well-being. Research on depression had already documented a downward spiral in which depressed mood and the narrowed, pessimistic thinking it brings, influence one another reciprocally, leading to ever worsening functioning and moods, and even clinical levels of depression. In contrast, the broaden-and-build theory predicts a comparable upward spiral in which positive emotions and the broadened thinking they bring also influence one another reciprocally, leading to appreciable increases in functioning and well-being (Fredrickson & Joiner, 2002). Fredrickson and Joiner (2002) examined affective experiences and broad-minded coping (e.g., considering different ways to deal with problems) across two assessment periods, five weeks apart. They found that the effects of positive emotions on well-being increased over time, creating an upward spiral towards enhanced well-being. Positive emotions predicted improved broad-minded coping, which in turn, predicted increases in subsequent experiences of positive

emotions. And again, new experiences of positive emotions enhanced future coping behavior, and so on.

In line with this conceptualization, recently, we have found that positive emotions help to build psychological resources that are essential in coping effectively with traumatic circumstances, such as the September 11, 2001, terrorist attacks on the United States. As part of our ongoing research on positive emotions and resilience, we studied a sample of students prior to the terrorist attacks. This afforded us the opportunity to make a prospective assessment of the benefits of psychological resilience and positive emotions in this crisis. We found that higher psychological resilience was associated with greater experiences of positive emotions, such as gratitude, interest, and love amidst negative emotions, such as anger, sadness, and fear. In addition, higher resilience was linked to postcrisis growth (indexed by increases in optimism, subjective well-being, tranquility). In line with the broaden-and-build theory (Fredrickson, 1998, 2001), postcrisis experiences of positive emotions fully mediated the effect of psychological resilience on psychological growth after the attacks (Fredrickson, Tugade, Waugh, & Larkin, 2002).

### CONCLUSIONS

The broaden-and-build theory (Fredrickson, 1998, 2001) proposes that positive emotions are useful to health in many ways. They facilitate healthy behavior in the present by broadening one's thoughts and attention, which set the stage for creative and innovative pursuits when faced with negative situations. As well, positive emotions build personal and social resources, which serve as protective factors useful in promoting good health in the future. New research indicates that finding ways to cultivate meaningful positive emotions is a critical necessity for optimal physical and psychological functioning. Indeed, positive emotions are good for your health. With increasing research, we continue to empirically substantiate age-old folk theories about positive emotions and health that have persisted through time.

## ENDOGENOUS OPIOIDS, STRESS, AND HEALTH

---

The endogenous opioids are a diverse group of neuropeptides with widespread distribution throughout the central and peripheral nervous systems and with far-reaching behavioral effects. For centuries, learned scholars and physicians appreciated the potency of opium in its influence on the body. This led to the speculation that the body must contain sensitive receptor mechanisms that bind and respond to opium and related substances. Thus emerged the enigma of why humans and other animals would evolve receptors for substances of plant origin. Many suspected that the body manufactured its own opium-like substances, and by the mid 1970s the prototypic opioid enkephalin and endorphin peptides had been discovered and their receptors identified. The subsequent characterization of their functional significance has revolutionized our views of psychological stress and its role in the etiology and expression of certain chronic diseases.

The potential medical significance of the endogenous opioids held extraordinary promise. In the 19th century, Sir William Ostler referred to morphine as "God's own medicine" and prescribed it for treatment of systemic disorders such as diabetes, as well as for its analgesic and antidiarrhetic properties. Since that time, opioid neurohormones and neurotransmitters have come to be appreciated as key biochemical mediators of homeostasis with a putative role in the pathophysiology of stress. The body's endogenous opioid neuropeptide systems appear to serve, generally speaking, as extensive and complex inhibitory mechanisms that modulate the fight/flight reaction, thus supporting the maintenance of homeostasis in the face of intense environmental challenges. These newly discovered neurochemicals have become critical foci for understanding certain diseases of adaptation and, hence, for development of novel biobehavioral preventative and therapeutic strategies. In the years subsequent to their discovery, the endogenous opioids

have enjoyed a profoundly significant and continually developing role in the psychophysiology of stress in behavioral medicine.

### CLASSIFICATION AND TERMINOLOGY

The term *opiate* generally refers to substances derived from opium, while *opioid* is a broader classification that includes not only the opiate alkaloids but also the various other substances with morphine-like affinity (binding strength) as well as activity (receptor stimulating action). Thus *endogenous opioids* refers to the general group of morphine-like bioactive peptides naturally synthesized within the body. Recombinant DNA studies suggest, based on separate precursor molecules, three major subgroups of opioid peptides: the endorphins, the enkephalins, and the dynorphins. As with catecholamine and other neurotransmitter systems, there are multiple subtypes of opioid receptors, based on relative affinity for selective agonists (stimulating substances) and antagonists (blockers). Opioid agonists show both affinity and activity at the opioid receptor level. In contrast, opioid antagonists show opioid receptor affinity without activity, and their competition for binding sites displaces or blocks access of agonists. Many opioids display mixed agonist-antagonist properties with affinity and limited activity profiles. Detailed discussion of the biochemical classifications of endogenous opioids and their multiple receptor subtypes is beyond the scope of this entry. It is sufficient to state for the present purpose that the endogenous opioids are not a singular unified system, but rather they constitute a diverse network of neuropeptides functioning as hormones and neurotransmitters, associated with several distinctive receptor systems. The anatomic diversity of opioidergic structures yields, in turn, a similar diversity of function, with widespread influence on behavioral and physiological effector systems.

### ANATOMIC DISTRIBUTION AND FUNCTIONAL SIGNIFICANCE

Endogenous opioid peptides and/or receptors are found localized within both central and peripheral nerve cells as well as within endocrine and other target structures throughout the body. Opioids appear to have both excitatory and inhibitory effects on other systems. Opioids are prominent in pathways mediating the stress response, and there is also a rich representation

of opioids in brain areas mediating reward and reinforcement. Elaborate opioid projections are found in afferent and integrative pain nuclei, as well as in the two major stress effector pathways, the hypothalamic-pituitary-adrenocortical (HPA) axis and the hypothalamic-sympatho-adrenomedullary (SAM) axis. Enkephalins have a widespread distribution throughout the limbic and sympathetic systems, while endorphin-containing cells are especially prominent in the hypothalamus and in the anterior pituitary. Dynorphins are widely represented in both central and peripheral nervous systems. The following briefly overviews the major sites for opioid interaction with neural and endocrine structures mediating systemic reactions to behavioral stressors and other intense stimuli.

### Opioids and Pain Regulatory Systems

The well-known analgesic effects of morphine stimulated an initial search for endogenous opioids and opioid receptors in pathways associated with transmission of pain-relevant impulses. As predicted, a major anatomical distribution of opioid peptides and receptors corresponds roughly to structures related to the perception of, and integrated response to, painful stimuli. For example, enkephalins are found in spinal cord areas associated with transmission of pain impulses and are also widely distributed throughout the limbic system in areas mediating the emotional response to pain. Endorphins are localized in brain areas such as the anterior hypothalamus, innervating the descending pain inhibitory pathways in the parabrachial gray. These anatomical sites of action are consistent with the analgesic properties of many opiates, and point to opioids as mediators of some forms of endogenous analgesia. Both opioid and nonopioid systems work together to form an important and complex endogenous analgesic mechanism, activated by stress and sensitive to classical conditioning and other behavioral manipulations. One endogenous analgesic mechanism has been recently linked to blood pressure baroreflex activity, but the relationship to stress-induced analgesia and the relative role of opioid and nonopioid mechanisms remain to be fully explored.

It has long been recognized that opiates do much more than simply inhibit pain sensation. Notwithstanding their euphorogenic effects, they also appear to render pain-producing stimuli less threatening. This observation reinforces the notion that endogenous

opioid systems play an important role in the higher-level integration of pain perception and in the emotional or affective integration of aversive and/or intense stimuli in general.

### Opioids and Pituitary Function

Consistent with the expansive role of endogenous opioids in the integration of systemic responses to intense stimuli, opioid peptides and receptors are found in hypothalamic and pituitary structures critical to maintenance of homeostasis during stress. For example, beta-endorphins are localized in the anterior and intermediate pituitary and some are costored and coreleased with adrenocorticotrophic hormone (ACTH) under control of corticotropin-releasing factor (CRF) from the paraventricular hypothalamus. Thus, systemic pituitary release of beta-endorphin typically corresponds with activation of the HPA cascade so important in the integrated response to psychological and physical stressors.

Endogenous opioids are also important regulators of hypothalamic cells that control both the anterior and the posterior pituitary. There is a growing appreciation of opioid influences on the stress-induced pituitary release of ACTH and prolactin. There are also important opioid mechanisms that influence release of growth hormone and luteinizing hormone. In the posterior pituitary, endogenous opioids inhibit release of both vasopressin and oxytocin. Thus endogenous opioids can influence regulation of the HPA axis as well as other important neuroendocrine pathways.

### Opioids and the Sympathetic Nervous System

The other primary effector pathway for the stress response is the SAM axis, which activates the peripheral sympathetic nervous system and the adrenal medullae via central autonomic control mechanisms in the hypothalamus and elsewhere. There is ample evidence to suggest that opioids can inhibit sympathetic and adrenomedullary responses at multiple levels of the SAM axis. For example, enkephalins are found in several autonomic ganglia and in the spinal sympathetic intermediolateral cell column. Enkephalins inhibit release of catecholamines from peripheral sympathetic nerve endings and from the adrenal medullae. Central opioids appear to regulate the balance between the sympathetic and parasympathetic nervous systems. Hence, both the SAM and the

HPA axes are subject to inhibition by endogenous opioid mechanisms.

The present body of data suggests that endogenous opioids function as major inhibitory mechanisms, limiting and terminating systemic reactions to stress, and helping to maintain visceral and affective systems within acceptable limits. Thus, major stress effector pathways appear to function under control of a pervasive and diverse endogenous opioid inhibitory system. It appears reasonable to hypothesize that abnormalities of inhibitory opioid function could disrupt important integrative mechanisms and thereby render an organism vulnerable to stress-induced disease processes.

## CLINICAL IMPLICATIONS

Most scientists will agree that the stress response has adaptive significance, especially in anticipatory preparation for the physical exercise of fight or flight. However, it is also widely believed that prolonged, exaggerated, or inappropriate behavioral and/or physiological responses to stress can have pathological consequences. Thus, overly exuberant reactivity to stress is implicated in the developmental etiology of certain diseases of adaptation, including some circulatory, neurological, and psychological disorders. This naturally leads to the notion that diminished function of endogenous opioids could leave the sympathetic nervous system, the HPA axis, and behavioral effector systems disinhibited and thus hyperreactive to psychological stressors. Hence, there may be deterministic relationships between the functional status of endogenous opioid systems and certain manifestations of stress-induced physio- and psychopathology. The following sections briefly detail recent research results on the relationship between endogenous opioids and stress mechanisms in health and disease.

### Opioid Dysfunction in Cardiovascular Disease

There are several lines of evidence linking hypertensive and atherogenic processes to exaggerated sympathetic nervous system responsivity. Hence, both of these disease processes may be influenced by the behavioral and physiological response to stress. For example, the early stages of essential hypertension are characterized by excessive activity of the sympathetic nervous system, with a characteristic pattern of blood pressure dysregulation during stress. Offspring of

hypertensive parents and young people with mildly elevated resting blood pressure show exaggerations of both sympathetic and circulatory stress responses. The role of this exaggerated sympathetic and circulatory reactivity in the etiology of essential hypertension remains to be fully understood, but there are numerous reasons to suspect some causal relationship with opioid alterations. Recent work with the opioid antagonists naloxone and naltrexone suggests that opioids inhibit sympathoadrenomedullary and blood pressure responses to stress in young persons with normal circulatory risk profiles. However, young persons at increased risk for hypertension show reduced opioid inhibitory effects on sympathetic, HPA, and circulatory responses to stress. This apparent dysfunction of inhibitory opioids may underlie exaggerated blood pressure reactivity to stress and its attendant health consequences. Further suggestion of opioid dysfunction in the early stages of hypertension comes from findings of decreased pain sensitivity in hypertensive patients and normotensive persons at risk for later development of hypertension. Opioids are also implicated in silent myocardial ischemia associated with reduced cardiac ischemic pain.

### Chronic Pain

There is an ample literature linking endogenous opioids to acute pain sensitivity, and these systems may also play an important role in chronic pain syndromes. Some theories of chronic pain suggest that endogenous pain regulatory systems, including both opioid and nonopioid systems, may become ineffective upon prolonged painful stimulation. The opioid depletion hypothesis proposes that prolonged exposure to pain stimuli can result in depletion of endogenous opioid analgesic neurochemicals or downregulation of opioid receptors, thus resulting in breakdown of an important psychophysiological mechanism for coping with chronic pain. Apart from their putative role in the basic pathophysiology of chronic pain syndromes, a major focus of current research is to develop better opioid-based analgesics while simultaneously minimizing their addictive potential.

### Posttraumatic Stress Disorder

Endogenous opioids play an important role in coping with traumatic stress and dysfunction of these systems

may be involved in posttraumatic stress disorder (PTSD). Administration of opioid blockers to patients with PTSD results in a constellation of changes that offer clues to the role of opioids in the body's response to prolonged and extreme stress. For example, acute administration of opioid antagonists increases PTSD symptomatology, suggesting that endogenous opioids play a salubrious role in coping with traumatic stress. Opioids appear to mediate a type of classically conditioned stress-induced analgesia observed in traumatized combat veterans. One current formulation is that persons exposed to traumatic stress may utilize their endogenous opioid analgesic and/or affect regulatory mechanisms to cope effectively. Symptoms of PTSD may thus emerge when opioid function is compromised via depletion of endogenous opioid stores, downregulation of opioid receptors, or exposure to opioid antagonists. Additional work is required to more fully evaluate opioid-based pathological mechanisms and therapeutic strategies in PTSD.

### Self-Regulatory Behaviors

Given the importance of intact opioid function in the adaptive behavioral and physiological adjustment to stress, it is likely that opioids play a broader role in self-regulatory behaviors related to substance abuse and appetite dysregulation. The euphorogenic effects of opiates, combined with anatomical and functional representation of endogenous opioids in brain structures associated with reward and reinforcement, illustrate the potential importance of opioids in appetitive mechanisms. By logical extension, alterations in the efficacy of opioid mechanisms may accompany abnormalities of various appetitive self-regulatory behaviors.

Basic research shows release of endogenous opioids during rewarding brain stimulation, suggesting a role of opioid mechanisms in the neural bases of positive reinforcement. If some of the maintaining mechanisms in substance abuse and/or appetite dysregulation are mediated via endogenous opioids, then treatment strategies targeting opioid systems may be potentially efficacious. This possibility finds partial support in studies of the effects of opioid antagonists in treatment for substance abuse disorders. There are a growing number of studies suggesting that treatment with opioid antagonists may facilitate abstinence in alcoholism, smoking, and other dependencies, and

may also facilitate control of appetite in obesity. Therefore, increasing appreciation of the important role of endogenous opioid neuropeptides in mediation of CNS reward systems may point to better management and treatment strategies in substance abuse and other disorders of appetite regulation.

### Opioid Mechanisms in Treatment and Prevention

It appears that dysregulation of endogenous opioid systems, through either opioid excess or deficiency, can contribute to disease etiology. It has been noted that blockade of opioid receptors may provide some benefit in disorders of self-regulatory behavior and possibly PTSD as well. In contrast, deficiency of sympathoinhibitory opioids appears to contribute to circulatory dysregulation during stress and to chronic pain syndromes. Thus endogenous opioid dysfunction has been linked to pathophysiologic processes associated with altered pain sensitivity, altered responsivity of the HPA and SAM axes, and dysregulated appetitive reward systems. Opioids may therefore play an important role in therapeutic and preventative interventions. Interestingly, studies of aerobic fitness, relaxation, and exposure therapies suggest that several forms of behavioral stress management operate via activation of inhibitory opioid mechanisms. Restoration of normal opioid function has been observed in some stress-management interventions with therapeutic and preventative potential. Targeting of disordered opioid inhibitory mechanisms may provide novel strategies for development of new behavioral and pharmacological treatments.

### SUMMARY

The endogenous opioid neuropeptides and receptors form a diverse neural and endocrine system that modulates reactions to pain, stress, and other intense stimuli. These mechanisms have become critical foci for understanding disease-relevant individual differences in the systemic response to psychological stressors and other intense stimuli. A body of data has emerged on the role of endogenous opioids in modulation of the physiological and behavioral response to stress in certain diseases of adaptation and self-regulation. Dysfunction of opioid inhibitory systems may leave an organism vulnerable to the pathophysiological effects of stress and other intense stimuli. These findings have compelled a search for the possible ways

that behavioral and pharmacological manipulation of endogenous opioids can form the bases for novel therapeutic strategies. Better understanding of these important morphine-like neuropeptides and their systemic consequences may provide insight into the developmental etiology and treatment of diseases of adaptation characterized by pathological bodily and affective reactions to stress.

## ERECTILE DYSFUNCTION

---

Erectile dysfunction refers to a man's inability to attain, or to maintain, an erection that is sufficient for sexual intercourse. This difficulty has also been referred to as *impotence*, a term that is no longer preferred because it is pejorative. Some men with erectile dysfunction report that they are completely unable to obtain an erection; however, it is more common for

men to report that they are able to obtain a partial erection that is too soft to achieve penetration or that they are unable to maintain their erection long enough to permit intercourse. Men with erectile difficulties often report that they feel less masculine and are embarrassed by the dysfunction; a minority of men report that they feel depressed.

### PREVALENCE

The commonness of erectile dysfunction is suggested by the numerous advertisements that appear on television and in men's magazines and by an active and flourishing commercial interest in medical treatments. Scientific studies provide more precise estimates and suggest that 10% of men report difficulty achieving or maintaining an erection (Simons & Carey, 2001). Several studies demonstrate that prevalence increases with age; for example, Laumann, Paik, and Rosen (1999) reported prevalence rates of 7% among men aged 18 to 29, 9% among men 30 to 39, 11% among men 40 to 49, and 18% among men 50 to 59. Chronic illness such as diabetes and cardiovascular disease increase the prevalence of erectile dysfunction, as does the use of alcohol and other drugs (including some prescription medications) and smoking.

### ETIOLOGY

Erectile dysfunction can be caused by a number of biological, psychological, and social factors. Biological causes can be subdivided into indirect and direct factors. Indirect factors are medical conditions that have no direct pathophysiological influence, but increase fatigue or diminish sexual arousal. For example, a man with chronic obstructive pulmonary disease may feel out of breath during sexual activity and his breathlessness may cause worry and result in erectile failure. Conditions such as diabetes and cardiovascular disease directly inhibit the vascular and neurological mechanisms needed to respond sexually.

Acute alcohol intoxication can impair male sexual arousal temporarily, but can undermine a man's confidence if persistent. Chronic alcohol abuse is more likely to impair sexual functioning on a regular basis due to nerve, testicular, and liver damage. The effects of other drugs are less well studied. It has been suggested that the frequency of erectile dysfunction among heroin users is 28% to 43% and among methadone users is 40% to 50%. Reliable estimates are

not available for other commonly abused substances (e.g., amphetamines, marijuana, cocaine). A number of prescription medications also impair erections.

Numerous psychological factors have been linked with erection problems. Anxiety has been suggested as an etiological factor by several theorists. William Masters and Virginia Johnson (1970) highlighted the importance of performance-related anxiety in particular. David Barlow and his colleagues have found that, compared to nondysfunctional men, men who experience erectile disorder tend to underestimate the amount of erection they are actually achieving, decrease their erection response when demands to get aroused are made, and display negative affect in the presence of erotic stimulation. Barlow (1986) concluded that cognitive interference and negative affect specific to sexual stimuli are central to erectile dysfunction.

Relationship difficulties can impair erections in men. For example, studies have found that dysfunctional men were more likely than sexually functioning males to report more frequent arguments and other deficits in the nonsexual aspects of their relationship (McCabe & Cobain, 1998). Clinical experience suggests that anger toward a partner and lack of trust in a relationship increase risk for erectile dysfunction.

## BEHAVIORAL TREATMENT OF ERECTILE DYSFUNCTION

The behavioral treatment of erectile dysfunction, often referred to as “sex therapy,” begins only after well-trained health care professionals complete a comprehensive assessment that yields information about the causes of the dysfunction (Ackerman & Carey, 1995). For many men, behavioral sex therapy will serve as the primary treatment because the erection problems are caused primarily by psychological or relationship factors; for men in whom biological factors are the primary cause of their erection difficulties, behavioral sex therapy can supplement medical treatments (such as Viagra) to optimize sexual functioning. In either application, behavioral sex therapy has several components (Wincze & Carey, 2001).

## EDUCATION

Sex therapists routinely provide information to correct myths and misunderstandings that adversely affect sexual functioning. For example, the belief that foreplay is for courtship only, or that intercourse is the

only true form of sex, can undermine sexual functioning among middle-aged or elderly men and their partners. Similarly, the belief that the erection must appear before sexual activity begins can limit a man’s sexual opportunities. Education about basic anatomy and physiology, normative sexual behavior, and changes in male and female functioning due to aging is frequently helpful.

## Sensate Focus

Sensate focus exercises, developed by Masters and Johnson (1970), involve discontinuing attempts at intercourse in the early stages of therapy, so that a man and his partner can relearn the basics of being affectionate as well as giving and receiving pleasure. Later, intercourse is reintroduced into their sexual repertoire only after a couple has relearned how to enjoy touching, holding, and kissing.

### *Principles*

Sensate focus exercises are guided by five basic principles. The first recognizes the importance of working with couples, not just identified “patients.” Sex therapists involve both the man and his partner, and recognize that the thoughts, feelings, and behavior of both are important.

Second, sensate focus involves helping a person or a couple to focus on, and develop a heightened awareness of, sexual sensations (rather than sexual performance). Through this, the couple reduces anxiety by striving toward outcomes that are rewarding and achievable (i.e., giving a back rub) rather than striving toward performance goals (e.g., achieving an erection).

Third, sensate focus is structured in that the therapist gives the couple explicit instructions for intimacy; if these instructions are followed, the partners will gradually regain confidence in themselves and in their relationship. However, sensate focus is also flexible in that it can be accommodated to a couples’ unique circumstances.

Fourth, sensate focus involves a gradual approach to change. Theoretically, the procedure of breaking down a complex behavior into smaller steps resembles behavioral “shaping” and facilitates self-efficacy through modest but attainable success experiences; an alternative conceptualization of sensate focus exercises is that they involve an in vivo desensitization procedure that facilitates anxiety reduction.

Finally, sensate focus involves sexual “exercises” that are completed at home to supplement therapy sessions.

### *Procedures*

Sensate focus involves homework and office-based meetings. The homework involves exercises that are typically broken down into sequential phases. The first phase discourages intercourse and encourages nongenital pleasuring or touching while both partners remain dressed. The idea is for partners to begin at a level that is likely to be successful, and involves no performance pressure. The homework assignment may include back rubs or holding hands with variations regarding who initiates, the types of behaviors participated in, and the length and frequency of sessions. After this initial phase, the couple’s experiences and reactions are discussed in the therapy sessions.

The second phase often involves “genital pleasuring,” in which partners extend gentle touching to the genitals and breasts. Partners are encouraged to caress each other in a way that is pleasurable. As before, the couple is discouraged from focusing on performance-related goals (i.e., getting an erection). During therapy sessions, the therapist asks the partners about their experiences and emotional reactions.

Once a couple becomes comfortable with genital touching, the third phase involves the resumption of sexual intercourse; however, this is sometimes broken down into several behaviors, for example, containment without thrusting. The final phase of sensate focus includes intercourse with thrusting. The couple is encouraged to focus on the sensations associated with intercourse and not to be concerned about erections or orgasm. The partners might be encouraged to experiment with different positions.

Through the sensate focus exercises, courtship skills are renewed, and new behaviors are learned as a couple transitions from a performance-based to a pleasure-based approach to sex. Sensate focus may also help to change patients’ perception of their partners. Many men approach sexual intimacy with intercourse and orgasm as the only goals. A partner may begin to see herself as only an object and not as a companion who is loved. The sensate focus procedure can help partners to treat each other with mutual affection rather than as sex objects. Sensate focus also offers an opportunity for individuals to learn to communicate with their partners about sexual pleasures and preferences.

It should be noted that sensate focus is one component of a total treatment approach; it is not a complete therapy in itself. Thus, communication issues, faulty attitudes that interfere with sexual enjoyment, and nonsexual marital conflicts are examples of therapy concerns that may be dealt with concomitantly with sensate focus.

### **Stimulus Control and Scheduling**

Stimulus control refers to efforts to establish a pleasant, relaxing, and erotic environment that is conducive to sexual expression. Time pressures, preoccupation with other responsibilities, and the presence of disruptive stimuli in the immediate environment can impair sexual arousal and functioning. Sex therapy often involves helping couples to schedule occasions for sexual intimacy during times when they are not tired or distracted. Scheduling is designed to overcome the myth that sex should not be planned. Couples are encouraged to schedule time for each other and to plan for it with as much effort as they might for any other special event in their lives.

### **Cognitive Restructuring**

Research suggests that challenging negative or maladaptive attitudes toward sex and reducing interfering thoughts can be helpful components of sex therapy.

Exposing and helping people to change negative attitudes is a complex therapeutic task. Maladaptive attitudes often persist, despite compelling data to the contrary. For example, a man with erection difficulties may have an untrusting attitude toward sexual partners because of an earlier relationship. This experience may generalize to the point that he perceives all partners similarly, despite the fact that not all people are alike. His difficulties may be a reflection of his fear of making a commitment and being manipulated. This attitude would be addressed before working directly on the sexual problem.

Some men (and their partners) may report intrusive images or thoughts that are interfering with sexual enjoyment. The presenting problem may be loss of erection, but the source of the problem is the interfering thoughts. Men sometimes dismiss such interfering thoughts as contributors to sexual difficulties, and focus instead on the perception of their own “inadequacy.” To counter such interfering thoughts, therapists

first help patients to recognize the presence of such thoughts and then to reduce their occurrence by, for example, encouraging patients to focus on erotic thoughts during sexual activity. An alternative strategy involves having patients “compartmentalize” thoughts. Specific times during the day should be set aside to focus on problem-solving; other times are then set aside for erotic thoughts. Putting such categories of thoughts on schedule helps to teach a patient to eliminate negative thinking during sexual encounters.

Negative beliefs and interfering thoughts can present impediments to sexual expression and enjoyment. In some cases, it will be possible to address these cognitive difficulties as a part of the sex therapy itself. In other cases, however, more intensive cognitive restructuring may be needed, usually in the context of individual therapy.

### Communication Training

Communication problems are encountered frequently when dealing with erectile dysfunction. Therapists typically work with couples to help them to improve their listening and communication skills and to provide couples with feedback based on their behavior during therapy sessions. Many therapists also used educational materials and role-play exercises to help couples to communicate more effectively. Therapists also strive to model strong communication skills in their own interactions with patients. This is achieved by listening actively, displaying empathy, asking patients to express themselves clearly, and other techniques.

### Evidence for the Effectiveness of Sex Therapy

Research over the past three decades has established that behavioral treatments for erectile dysfunction can be highly effective when implemented with men whose dysfunction involves psychosocial causes (Heiman & Meston, 1997).

## EVIDENCE-BASED BEHAVIORAL MEDICINE

---

Evidence-based behavioral medicine (EBBM) is the conscientious review and application of previous literature on behavioral interventions to current practice. Interest in EBBM grew out of the evidence-based medicine movement in the medical sciences that began in Canada about 10 years ago and is now an international effort (Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). Evidence-based medicine is methodologically applying recent relevant research to clinical questions to inform clinical practice (Rosenberg & Donald, 1995). That is, a clinician reviews recent research evidence or published evidence-based practice guidelines and, in combination with judging the needs for this patient, applies the most efficacious treatment. This process is differentiated from traditional biomedical research in which one relies primarily upon previous training, the most popular practices, and personal experience to address patients' needs. For example, recent evidence from a randomized, placebo-controlled trial suggests that arthroscopic surgery is not superior to sham surgery in treating osteoarthritis of the knee (Moseley et al., 2002). Thus, an EBBM practitioner may decide to

treat osteoarthritis of the knee pharmaceutically, whereas a traditional practitioner may still perform arthroscopy. In addition to the enhancement of patient care, EBBM was initiated to provide researchers and reviewers more practical and systematized ways to communicate with practitioners and policy advocates.

The chain of reasoning for the existence of the evidence-based movement is as follows: (a) patient care can be enhanced if empirical knowledge about behavioral treatments is constantly available, (b) practitioners cannot easily access this knowledge in its current form, (c) practitioner knowledge and skills are subsequently outdated because of the difficulty in obtaining this knowledge, and (d) easily digestible, standardized summaries of the evidence base and regular reviews of this knowledge base by experts, as well as the location and availability of intervention resources, will improve this situation. The social sciences, including clinical psychology and behavioral medicine, began endorsing the importance of systematically reviewing evidence that supports, or refutes, the use of certain treatments only 5 years ago, suggesting that this nascent field is still developing.

EBBM can allow researchers, practitioners, health policy developers, and patients the means by which to evaluate the strength of evidence that exists for a certain behavioral medicine treatment and judge whether the likely benefits of the treatment will outweigh the risks. Ideally, EBBM offers a systematized process by which to consider the evidence available for each treatment so that the best treatment can be chosen for patients with joint medical and psychosocial issues.

#### WHY IS EVIDENCE-BASED BEHAVIORAL MEDICINE IMPORTANT?

Although there are many behavioral medicine treatments and issues for which little evidence yet exists, by promoting EBBM principles researchers and reviewers can be guided to the next level of research that must be conducted to further the evidence base available for the behavioral medicine field. For example, in one area of behavioral medicine, careful review of the evidence available for the psychometric rigor and prognostic usefulness of competing assessment tools may forward standardization of assessment. In another area, the presence of one controlled trial may suggest that further trials, conducted by another investigator or by another laboratory, is now required to test the generalizability of the intervention.

By offering a standardizing approach to the development, test, review, and implementation of behavioral medicine treatments, everyone benefits. Thus, using evidence-based principles allows various audiences to judge the value of certain behavioral medicine interventions and concepts and to consider the ways in which these treatments can best be used or further studied. The ability to inform policy, public health issues, and reimbursement is enhanced when the evidence base is strong and incontrovertible for certain interventions. This type of base only occurs when research is informed by evidence-based thinking.

#### THE DEVELOPMENT OF EVIDENCE-BASED BEHAVIORAL MEDICINE

The U.S. Preventive Services Task Force (USPSTF), a faction of the U.S. Department of Health and Human Services, was developed two decades ago to address similar issues regarding the application of research findings to policy regarding physical health in the form of recommended guidelines for practitioners. They produced the *Guide to Clinical Preventive Services* in 1989, which included a review of evidence on various tests and interventions as well as a five-level score evaluation of the evidence presented. This publication suggested a manner in which the level of evidence could be graded, and when the evidence base was sufficiently developed, practice, insurance, and policy on preventive services could be changed. The USPSTF (currently in its third reincarnation) is funded by the Agency for Healthcare Research and Quality (AHRQ; Woolf & Atkins, 2001). AHRQ, formerly known as the Agency for Health Care Policy and Research, is the body of the Department of Health and Human Services authorized by the U.S. Congress to support improvements in health services, strengthen quality measurement and improvement, and improve health care access, foster appropriate use, and reduce unnecessary expenditures. Two other organizations that systematically review the available literature and disseminate their findings are the Cochrane Collaboration, which focuses on health care interventions, and the Campbell Collaboration, which focuses on social and educational policies and practices.

Both AHRQ and USPSTF have expanded their review of evidence-based practice to include behavioral medicine interventions. For example, AHRQ published clinical practice guidelines titled *Treating Tobacco Use and Dependence* in June 2000 (updated

1996 version) to assist clinicians identify and evaluate the treatment options (both psychological and pharmaceutical) available to their patients. In addition, behavioral counseling interventions for reduced risky drinking, improved dietary practices, and increased physical activity were systematically reviewed and subsequently evaluated in a recent paper published by affiliates of USPSTF (Whitlock, Orleans, Pender, & Allan, 2002). These publications are evidence of government support of the evolution of EBBM from EBM.

Behavioral medicine researchers have developed their own organizations to review interventions. The Clinical Psychology Division of the American Psychological Association created a task force that initiated the use of guidelines in evaluating empirically supported psychotherapy interventions. In addition, a contract was awarded to the Society of Behavioral Medicine by the Office of Behavioral and Social Sciences Research to evaluate the need for evidence-based principles for behavioral medicine. This committee, the EBBM Committee, is mandated to develop guidelines to help clinicians, researchers, and educators use the available research on behavioral interventions to inform clinical work.

## LIMITATIONS OF EVIDENCE-BASED BEHAVIORAL MEDICINE

Several limitations have been reported in using EBBM. For practitioners, there are serious obstacles in the ways in which research findings can be used to inform practice. They want to be aware of and have the best tools to treat their clients, although they do not want to be restricted in their use of nonevidence-based tools. This is thought to happen if certain treatments are privileged over others, based on the available evidence. Alternative or newer treatments may not have received the attention and funding for the necessary research to compile a sufficient body of evidence for comparison with more traditional treatment modalities. Practitioners also may not have training in evidence-based recommended procedures.

The medical community discovered that the reporting of randomized clinical trials (RCTs) was inconsistent and substandard. Incomplete reporting of recruitment, randomization procedures, and multiple exploratory analyses reduced the likelihood of an accurate evaluation and understanding of the clinical methods and findings of a study. Therefore, reporting

guidelines for RCTs, known as the CONSORT Statement, were developed and consequently endorsed by hundreds of medical journals internationally. These guidelines were implemented so that various audiences, from stakeholders to policymakers, could evaluate the likelihood that the tested intervention could improve health.

The CONSORT Statement has been criticized for its focus on the reporting of characteristics that are pertinent to internal validity, or the extent to which the design and the conduct of the trial eliminate the possibility of bias. External validity, or the generalizability of one's study outcomes to the population of interest, is of particular interest to behavioral medicine researchers. Specifically, many of our interventions and research efforts are aimed at diverse populations and/or units of analysis for which generalizability issues are particularly pertinent. The issues that need to be reported to allow the consideration of external validity factors are included in the RE-AIM Framework, developed by Russell Glasgow and his colleagues.

The RE-AIM framework addresses individual and organization level areas of assessment through an evaluation of the reach, efficacy, adoption, implementation, and maintenance of behavioral medicine and other interventions. Reach (individual level) is the generalizability of the results to the correct population or unit of analysis and includes consideration of the rates of exclusion from an intervention study, participation rate among eligible persons, as well as the representativeness of the participants. Efficacy (individual level) is the effect of the intended intervention on the prespecified outcome (an internal validity issue) and also the impact of the intervention on potential negative effects or adverse events. Adoption (organization level) is the uptake or the agreement to be in the study by the settings and the providers (intervention agents) who were invited to enter the study. Thus, a study may have very good internal validity and seem to have very promising findings, but if very few participants were eligible to enter into the trial and almost no settings or providers were willing to be in the trial, the intervention is unlikely to be adopted by other settings or have broad public health impact. Implementation (organization level) represents a consideration of the costs (either in dollar value or in time) to provide an intervention as well as the types of providers required to successfully deliver the differing components of an intervention. Hence, if an intervention requires substantial physician time to diagnose and refer, and then

additional nursing time to screen and schedule appointments, and finally psychotherapist time to deliver the group therapy, all of these human resources should be considered in the evaluation of the feasibility of that particular intervention. Finally, maintenance (both individual and organization levels) is a careful deliberation of the organizational and provider commitment to continue offering the intervention after the study is completed, as well as the participant's maintenance of the new behaviors/intervention. These generalizability issues, while infrequently discussed in medical evidence-based chapters, are considered extremely relevant to the EBBM movement.

Thus, the EBBM Committee has augmented the existing guidelines compiled by CONSORT with the RE-AIM criteria by Glasgow and his colleagues. The guidelines have also been expanded to include behavioral-medicine specific concerns, including treatment fidelity, provider and patient adherence and allegiance, and other issues specific to behavioral medicine prevention and intervention efforts (Davidson et al., in press).

## POLICY IMPLICATIONS OF EVIDENCE-BASED BEHAVIORAL MEDICINE

There is both concern and anticipation about the influence of EBBM on policy. It begins with the question of what is evidence and who has the power to define it. It continues through who reimburses and reinforces EBBM practices and it ends with what kind of overall benefit results for clients, and populations, in genuine health improvement. In some areas of medicine, the introduction of the evidence-based movement has resulted in the cessation of reimbursement of some medical practices, because the evidence suggested that these routines were harmful or only minimally beneficial, but there has been continuing lack of reimbursement for well-supported treatments, such as smoking cessation. Thus, lobbying efforts, politics, and sophisticated use of such models as the push-pull-delivery capacity model (Orleans, Gruman, & Anderson, 1999) are all needed to have policy appropriately informed by evidence bases.

## FUTURE DIRECTIONS

EBBM is a challenge but it is also an opportunity. It is an opportunity to gain credibility for behavioral medicine interventions and provide a forum for this to occur. In examining the movement as it has progressed in medicine, proposed treatments have been

successfully tested, improved, adopted, and finally certified as standard of care. In behavioral medicine, there are competing alternative treatments for similar disorders with little systematic evaluation of which is best. Without a process in place by which behavioral medicine interventions can progress to become a standard of care, the field may continue to be undervalued. An effort to influence policy cannot be successfully mounted without systematic evidence. Quality care for our patients, adequate reimbursement for clinicians, and appropriate and useful interventions to be taught to students also result from an evidence-based movement.

## EXPLANATORY STYLE AND PHYSICAL HEALTH

---

For the Western world, a historical view of how the healing professions have approached the treatment and prevention of illness reveals three major eras. Throughout most of history, up until the time that germ theory emerged in the 1800s, the focus was solely on disease treatment. People went about their lives until they fell ill; then physicians entered the picture and attempted to combat the illness.

In the second era, starting with germ theory, the focus expanded to disease prevention. Public health workers tried to prevent germs from entering the body. Swamps that hosted malaria-carrying mosquitoes were drained; surgeons began to wash their hands before and after they operated; food was inspected and dated for freshness. What these first two eras had in common is that the individual who was supposed to benefit from their approaches was passive. He or she did nothing except to go along with the efforts of the physician or the public health expert.

In the third and most recent era, taking form in just the past few decades, the focus shifted to health promotion. The person was called upon to make an active effort to behave in health-promoting ways. The related fields of health psychology and behavioral medicine exemplify this third era. In both fields, psychological factors are identified that contribute to physical well-being or its absence. Among these factors

are thoughts and beliefs, and this contribution surveys what is known about the role of a particular cognitive personality characteristic—explanatory style (also known as attributional style)—in health and illness.

## EXPLANATORY STYLE AND ITS MEASUREMENT

Explanatory style refers to how an individual habitually explains the causes of bad events. This cognitive personality variable is sometimes described as pessimistic (when bad events are explained with causes that are long-lasting [stable], pervasive [global], and internal to the self—e.g., “It is going to last forever; it will undercut everything; and it is my fault”) versus optimistic (when bad events are explained with causes that are transient [unstable], circumscribed [specific], and external to the self—e.g., “It was a fluke”). Explanatory style is thought to be a distant influence on the specific expectation that one’s behaviors are related (or not) to important outcomes. A pessimistic explanatory style therefore encourages individuals to believe that they are helpless, that nothing they do matters, whereas an optimistic explanatory style encourages individuals to believe that their behaviors do affect outcomes. Accordingly, pessimistic people are prone to learned helplessness, and optimistic people are not.

Explanatory style began as its own line of research when measures of this individual difference were developed. The most often used measure is a self-report questionnaire called the Attributional Style Questionnaire (ASQ), which presents respondents with hypothetical bad events involving themselves and asks them to provide “the one major cause” of each event if it were to happen to them. They then rate these provided causes along dimensions of internality, stability, and globality. Ratings are combined by averaging.

A second way of measuring explanatory style is with a content analysis procedure—the CAVE (an acronym for Content Analysis of Verbatim Explanations)—which allows written or spoken material to be scored for naturally occurring causal explanations. Researchers identify explanations for bad events, “extract” them, and present them to judges who rate them along the scales of the ASQ. The CAVE technique has been used to analyze psychotherapy transcripts, diaries, interviews, open-ended questionnaires, political speeches, sports stories, religious texts, and song lyrics. The greatest methodological virtue of this approach to studying explanatory style is that it allows

longitudinal research to be conducted retrospectively. If suitable verbal material can be located from early in the lives of individuals whose long-term fate is known, then the CAVE technique allows studies to be done very quickly, which nonetheless span decades. For obvious reasons, studies of explanatory style and physical well-being have frequently relied on the CAVE.

## EXPLANATORY STYLE AND PHYSICAL WELL-BEING

Several dozen studies exist that have attempted to establish a correlation between explanatory style (measured with the ASQ or the CAVE) and physical well-being. Taken together, these studies converge to show that optimistic explanatory style predicts good health operationalized in a number of ways, from self-report to physician ratings of general well-being to doctor visits to survival time following a heart attack to immunological efficiency to longevity.

How strong is the association between optimism and good health? Most of the relevant studies report correlation coefficients in the 0.20 to 0.30 range, which are moderate in size and typical of correlations in psychological research. Research participants included males and females, some initially healthy and others initially quite ill. Adults across the lifespan were included. Many of these studies were longitudinal, spanning mere weeks to almost five decades. And at least some of these longitudinal studies statistically controlled for initial levels of health and potential confounds involving tendencies to complain.

Explanatory style apparently impacts health at a number of junctures. It can make the initial onset of illness less likely; it can minimize the severity of illness; it can speed recovery; it can make relapse less likely. Most of the relevant studies, by virtue of rather stark correlational designs, do not allow conclusions about when health is impacted. Nor do they establish causality. Future investigations of a more fine-grained nature are of course indicated.

## EXPLAINING THE LINK BETWEEN EXPLANATORY STYLE AND HEALTH

The most basic question that arises from research into explanatory style and health involves the mechanism linking the two. The link appears to be overetermined, and there are a number of plausible routes.

For example, there may be an immunological pathway. Some research suggests that optimistic explanatory style is positively correlated with the vigor with which the immune system responds to an antigen challenge. And several other studies have looked at how explanatory style is linked to the progression of AIDS. Results are mixed, but there are hints that optimism predicts survival time and that this effect is mediated in part by immunological factors.

There may also be an emotional pathway between explanatory style and health. An extensive research literature shows optimistic explanatory style to be incompatible with depression, and other studies have linked depression to poor health and early death. At least part of this latter path may be immunological.

There are probably several cognitive pathways between explanatory style and health as well. One's habitual style of explaining bad events is not an isolated belief, like an obscure phone number, but rather part of a complex knowledge system that can impact physical well-being in numerous ways. For example, individuals with optimistic explanatory style see the world as less filled with hassles than do their pessimistic counterparts; this tendency in turn is linked to better health. For another example, individuals with optimistic explanatory style believe that good health can be "controlled" (i.e., promoted and maintained).

Another explanation of why optimistic thinking is related to physical well-being points to a social pathway. People with a pessimistic explanatory style are often socially isolated, and social isolation is a consistent predictor of poor health.

In general terms, the individual's social context can set the stage for the link between explanatory style and physical health. In 1987, Leonard Sagan argued that the dramatic increase in life expectancy in the Western world over the centuries was due not to breakthroughs in medical or public health practices but instead to cultural diffusion of the originally radical notion that an individual is a discrete self able to have an effect on the world. Once the idea of individual agency was invented, legitimized, and disseminated, the findings so far discussed became possible.

The most typical and most robust mechanism is probably a mundane behavioral pathway. So optimistic explanatory style is associated with a variety of "healthy" practices: exercising, drinking in moderation, avoiding fatty foods, and the like. People with

optimistic explanatory style were more likely than their pessimistic counterparts to respond to colds with appropriate actions: resting and consuming more of Mom's chicken noodle soup.

In 1998, Christopher Peterson and colleagues reported a study of explanatory style and physical well-being that looked at more than 1,000 individuals over almost 50 years. Pessimistic individuals had an increased likelihood of an early death, and the large sample size made it possible to investigate associations between explanatory style and death due to different causes. In contrast to the intuitive hypotheses that death by cancer (long described as a "disease of despair") and perhaps death by cardiovascular disease would be especially linked to a pessimistic way of thinking, this study instead found that pessimistic individuals were most likely to die accidental and/or violent deaths. The effect was particularly pronounced for men.

Deaths like these are not random. "Being in the wrong place at the wrong time" may be the result of an incautious and fatalistic lifestyle entwined not only with pessimism but also with the male gender role. This study did not reveal what deceased research participants were doing when they died accidentally or violently, but Peterson and colleagues speculated that behavior was somehow implicated, if only by affecting the settings that individuals habitually entered or not.

A series of follow-up studies by Peterson's research group supported this hypothesis. First, they discovered that a pessimistic explanatory style predicted the likelihood of traumatic injuries requiring medical attention. Again, this effect was more pronounced for males than females, especially in the young adult years. Second, they showed that a pessimistic explanatory style was associated with a preference for potentially dangerous activities—e.g., driving recklessly or drinking excessively. Again, this association was more likely for males than for females. Third, they showed that this pessimism-driven preference for dangerous activities translated itself into risky behavior and actual trauma when individuals were in bad moods.

## CONCLUSIONS: IMPLICATIONS FOR PREVENTION AND TREATMENT

Can a lifetime of good health be encouraged by the early cultivation of optimism? Researchers at the University of Pennsylvania have described an intervention program that involves teaching grade-school

children to be more optimistic. Results suggest that optimism training makes subsequent episodes of depression less likely and may pay the added dividend of encouraging good health.

One can similarly ask if optimistic ways of thinking acquired once an individual falls ill will boost good health. Again, studies of optimism and depression suggest that this question is worth pursuing. Cognitive therapy that targets negative ways of thinking alleviates depression and prevents its recurrence. By implication, cognitive therapy for the seriously ill might have health benefits.

## EXPRESSIVE WRITING AND HEALTH

---

For centuries people have written poems, novels, and journal entries as a way to help them cope with disturbing personal events. Psychologists, on the other hand, have traditionally followed Freud's lead and favored a "talking cure." The idea that a "writing cure" may be at least as powerful was left unexplored until the mid-1980s, when researchers discovered that asking people to write about traumatic experiences improved their mental and physical health.

### A TYPICAL EXPRESSIVE WRITING EXERCISE

Most written disclosure studies have used the same basic procedure. Researchers arrange for people to come into the research lab on each of about 4 or 5 days. On the first day, the experimenter divides people randomly into two groups. Everyone is asked to write for 20 minutes each day, but the topic depends on which group they are in. Those in the expressive writing group are told something like this:

I would like for you to write about your very deepest thoughts and feelings about an extremely important emotional issue that has affected you and your life. In your writing, I'd like you to really let go and explore your very deepest emotions and thoughts. You might tie your topic to your relationships with others, including parents, lovers, friends, or relatives; to your past, your present, or your future; or to who you have been, who you would like to be, or who you are now. You may write about the same general issues or experiences or on different topics each day. All of your writing will be completely confidential. Don't worry about spelling, sentence structure, or grammar. The only rule is that once you begin writing, continue to do so until your time is up.

The remaining people in the study serve as a control group. Control participants write about nonemotional topics, such as how they manage their time. Neither group receives feedback about their writing. All participants are followed over a period of weeks or months to see if a difference in physical or mental health appears between the groups.

### THE EFFECTS OF EXPRESSIVE WRITING

Participants typically reveal deeply personal information, from childhood abuse to bereavement to the details of romantic relationships. In the short term, writing often upsets those in the expressive group. Nevertheless, in the long run, participants in the expressive writing group report being happier and healthier than controls. Many feel writing helped them to come to terms with disturbing events. Furthermore, their scores on formal measures of emotional well-being surpass those of people who write about a superficial topic.

Expressive writing can also lead to improved life chances: after writing, students get better grades and recently laid-off professionals find work more quickly. This could be because people who have had some kind of dramatic emotional experience often become preoccupied with it. They feel compelled to dwell on the issue (or ruminate), and experience intrusive thoughts about the event. Rumination and intrusive thoughts can consume considerable mental time and energy, taking up working memory resources that could otherwise be used for study or other tasks relevant to personal success. The writing task forces people to sit down and articulate the experience, label the emotions, and try to find some kind of coherence or meaning. This exercise alone may be enough to bring about cognitive change that reduces rumination and intrusive thoughts. Indeed, Kitty Klein reported that people's working memory increased after emotional writing, allowing them to process a greater range of information.

Most striking is that multiple experiments have found that expressive writing can improve people's physical health. In the weeks after writing, participants tend to go to the doctor less, take fewer sick days off work, and suffer fewer symptoms of chronic illnesses, such as rheumatoid arthritis. Yet the health benefits of writing are not simply due to inspiring people to take better care of themselves. Diet, exercise levels, and other health behaviors remain largely unchanged. Instead, writing reduces overall stress levels due, in part, to people no longer ruminating about the emotional upheavals. Heart rates and skin conductance levels (i.e., sweating) fall, indicating greater relaxation. Immune system responses strengthen. For example, expressive writing participants show increased antibody levels as part of enhanced immune responses to hepatitis B vaccinations.

Expressive writing also helps participants who test positive for the Epstein-Barr virus to keep the dormant infection under control.

#### WHAT MAKES FOR AN EFFECTIVE WRITING TASK?

The writing task can be structured and worded in many different ways, but certain features may be important. People should be told to aim for a coherent narrative that not only describes feelings but also discusses what (or who) those feelings are about. Simply writing down feelings without putting them into context does not work. Merely venting emotion is not enough. Research by Dan McAdams suggests that people have a fundamental need to create stories about themselves, and these stories are at the core of a person's identity. It makes sense that an expressive writing exercise has such enormous psychological impact, because it involves organizing and articulating people's life stories.

Writing certainly works if people are told to write about upsetting topics. The first writing studies, conducted by James W. Pennebaker and his colleagues, asked people to write about the most traumatic event of their entire lives. This fits with received wisdom of psychotherapists that effective psychotherapeutic work is and must be inherently painful. However, later research findings challenged "no pain, no gain" assumptions. Laura King reported improved health after writing, even for people who did not venture into deeply traumatic waters. For example, health improved for people who wrote about the positive aspects of negative experiences, such as having cancer, or about experiences that are likely to be a mixture of positive and negative, such as coming to college. Writing exercises do more than offer a safe space for confronting traumatic memories or thoughts. Writing may help someone to see a past experience in a new light, recognize the positive aspects of their current situation, or be more optimistic about the future. These findings mean that writing is a therapeutic option even for people who find it difficult to bear the short-term distress of a trauma-writing exercise.

#### WHO BENEFITS FROM WRITING?

People from all walks of life often benefit from emotional writing, compared to a control writing

exercise. Studies have found health gains for young and elderly people, for highly educated people and the barely literate, and for individuals with diagnoses of psychological disorders as well as individuals whose psychological health is generally good. Benefits have even been found for sex offenders in prison. Data from Europe, North America, Central America, and Asia all show positive results. Nevertheless, some people benefit more than others. For example, some studies have found that males benefit more than females, and hostile people benefit more than less hostile people. One possibility is that men and people with hostile personalities are less likely to have already expressed their emotions prior to writing.

Reading what people write can help researchers determine which people are most likely to show health improvements, and why. Pennebaker and his colleagues developed a computer program that counts how often different types of words appear in a passage of text. They found that participants whose essays contained a high number of positive emotion words (e.g., *pride*, *joy*) and a moderate number of negative emotion words (e.g., *sad*) showed greater benefits than people who did not use emotional words as often. An even better predictor of health improvements was a pattern of increasing use of cognitive words (e.g., *think*, *realize*, *because*) from the first to the last day of writing. Cognitive words often appear in stories or narratives. Those people who are able to put together a meaningful account of their traumas, then, may be the very people most likely to show improvements in health.

In a further study, Sherlock Campbell and Pennebaker used a technique that measured the similarity between different essays written over the course of 3 days. People who used different pronouns (e.g., *I* vs. *she* vs. *they*) on different days of the exercise showed greater health benefits. It may be that writing works if it provides an opportunity for a person to explore a particular experience from a variety of viewpoints, organizing the memory, and obtaining some distance from it.

#### HOW DOES WRITING COMPARE WITH TALKING?

Writing provides some of the same health benefits as talking to a therapist. This might come as a surprise, because people usually assume that the therapist's feedback is crucial. Indeed, rival psychotherapy

schools (e.g., feminist vs. Freudian) have had heated debates over the details of feedback techniques. Yet, writing involves no immediate feedback. Even if someone else will eventually read what the patient has written, the actual process of expressing emotional experiences through writing is completely one-sided. Indeed, the exercise works even if the patient plans to destroy the writing. The writer controls the topic, the order in which emotions and events are described, and the tone and language used to describe them. A related advantage is that the writing has no direct impact on other people, and so does not put relationships at risk in the way that expressing negative emotions to a close other can do.

Most critical is that emotions and emotional events are expressed in the form of words. Talking into a tape recorder works, but expressing emotion nonverbally does not. After expressive dance exercises, for example, people claim to feel better, but their objective health indicators are no different from those of a control group. The writing research, then, has helped to isolate one critical feature of psychotherapy: verbal emotional expression. This also happens to be a feature shared by nearly all psychotherapies. So, almost any type of psychotherapy is likely to be beneficial to some degree, as long as it provides the opportunity to express emotional events using words.

## HOW DOES EXPRESSIVE WRITING WORK?

The original explanation Pennebaker offered was that chronically avoiding disclosure of some highly emotional experience constituted a long-term stressor. Like other long-term stressors, this placed an extra burden on the body's immune system and other coping mechanisms. Writing was presumed to address this inhibition by allowing people to come to terms with unexpressed experiences. Once the events were expressed in writing, people would no longer be inhibiting thoughts and feelings about those events. This explanation fit with evidence that people concealing a stigma such as being gay were less healthy than those who were out of the closet. However, further research found that writing about

traumas that have already been disclosed to another person can be just as beneficial as writing about a true secret. It is not simply that being the sole witness to powerful experiences is sufficient to impede health.

An alternative explanation is that writing helps people put their psychological affairs into order, and that this order is in itself beneficial because it reduces rumination. As in the case of the inhibition explanation, the removal of this chronic stressor could improve health. This theory also explains why the exercise works even if people destroy their essays at the end of writing, because it could be the act of writing a story, not the act of communicating, that is beneficial.

Even if we do not know exactly why it works, the overall message from nearly 20 years of research on the relationship between writing and health is that most people would benefit from being given the time, privacy, and encouragement to write about their emotional experiences.

## FIBROMYALGIA SYNDROME: BIOBEHAVIORAL ASPECTS

---

### PREVALENCE AND DIAGNOSIS OF FIBROMYALGIA SYNDROME

Fibromyalgia syndrome (FMS) is a growing diagnosis in America with an estimated 2% to 6% of adults (4-12 million) but more women (estimated at 3.4-10.5%) than men (0.5%) having FMS. Prevalence increases with age and peaks between 50 and 80 years old. Several features of FMS overlap with other chronic painful and fatiguing conditions such as chronic fatigue syndrome (CFS), irritable bowel syndrome (IBS), and temporomandibular disorders (TMD), among others. These conditions share the dubious distinction of having no clear pathological markers, which precludes definitive tests, and so are diagnosed by symptoms and exclusion of other possible diagnoses. Many people display symptoms that meet diagnostic criteria for more than one of these conditions (Bennett, 1998); overlapping symptoms particularly include unexplained and enduring fatigue, diffuse or widespread muscle and joint pain, sleep disturbances, and activity intolerance. Many individuals with FMS also meet criteria for CFS, and many studies include subjects with either or the dual diagnoses. In this entry, the signs and symptoms for diagnosing FMS as well as the dominant underlying biobehavioral associated factors and potential functional alterations are discussed.

FMS is characterized by widespread pain (above and below the waist, in the right and left sides of the skeleton) for at least 3 months, pain when pressure is

placed on 18 discrete body locations (called tender points), and unexplained extraordinary fatigue (Wolfe et al., 1990). People also are likely to report other symptoms such as stiffness; numbness or tingling; sleep disturbances; headaches; stomach or bladder symptoms; and inability to concentrate, remember, or think properly, a condition that patients refer to as “fibro fog.” The consequences in the most severe cases include profound inability to perform activities of daily living and work. Susceptibility to FMS may run in families, and studies of genetic factors are emerging, particularly in relation to alterations in the brain chemical serotonin, which is active in regulating mood states, pain experiences, and behaviors such as sleep.

### THE LINK OF FMS TO LIFE STRAIN AND EMOTIONAL DISTRESS

Clinically, both onset and continuation of FMS symptoms are related to stressful, that is, physically and/or emotionally challenging, circumstances. Individuals who report high life strain as measured by exposure to negative life events, major ones and daily hassles; sexual, physical, or emotional abuse; and engaging in overactive mental or physical lifestyles are predisposed to FMS (Van Houdenhove et al., 2002). Individuals with FMS report more negative life events and they rate the events as more disturbing than people without FMS. The majority of people can pinpoint an onset event or a trigger such as severe infectious-like illness, physical injury (surgery, accidental trauma), or a circumstance evoking intense emotional upset.

According to the results of in-depth interviews, coping patterns vary across individuals. Some people

perceived managing their everyday life by mobilizing their physical and psychological strength to overcome the pain and fatigue, others by adjusting their activities according to what they assume as their limitations; some in despair no longer wanted to cope with their pain and life situation; and some had given up many activities of everyday life and felt that their symptoms dominated their life.

Patient delay in seeking treatment and clinician underrecognition of FMS and CFS means that people often receive a diagnosis and help with treatment only after years of suffering. People who have untreated psychiatric and physical illness, experience unrelieved life strain, and succumb to being very inactive with prolonged work absence are most at risk to have very protracted recovery times.

Some but not all people with FMS have a tendency to have mental illness in higher numbers than people with chronically painful diseases such as rheumatoid arthritis or multiple sclerosis. Depressed mood and anxiety are evident in large numbers of patients meeting criteria for FMS and CFS, and roughly 25%-30% of patients with FMS who present for treatment have major depression. Many have a lifetime history of major depression and panic disorder (Demitrack & Crofford, 1998) as well as high rates of familial major mood disorder. While psychiatric illness is often considered as an overlay on FMS (i.e., comorbid), the somatic and emotional manifestations of FMS could emanate from shared or common brain chemical (neuromodulator) disturbances. At issue is whether negative mood changes follow or precede the pain and fatigue symptoms of FMS/CFS or whether or not they are part of the overall syndrome.

#### LINKING LIFE STRAIN, DISTRESS, AND FMS PHYSICAL SYMPTOMS

The obvious connection of FMS to environmental life strain and personal emotional/mental distress has given rise to two main lines of investigations to help explain FMS symptoms, particularly pain and fatigue. One line involves disturbances in the stress nervous and hormone systems, that is, the autonomic nervous system and the interactive features of the hypothalamus, pituitary, and adrenal glands (called the HPA axis). The other investigative line involves brain and spinal cord chemical neuromodulator disturbances that likely underlie unusually heightened pain sensitivity.

#### Changes in the Stress

##### Nervous and Hormone Systems With FMS

Several changes in stress-related hormone patterns and functions are seen in people with FMS (Demitrack & Crofford, 1998). Stress hormones (e.g., epinephrine, norepinephrine, cortisol) normally fluctuate as individuals adapt to any unusual and challenging environmental circumstances. A healthy, normal pattern includes elevation of these hormones and return to resting levels within short periods of time as one adjusts to the special situations. A large portion of this activation involves the sympathetic nervous system (SNS) with release of epinephrine and norepinephrine into the bloodstream and into tissues. This serves to create a number of alerting bodily changes that prime for defending against danger or harm, the sum total of which was historically called the fight-or-flight response. In some individuals, this protective activation pattern is prolonged and enduring, perhaps due to inherent behavioral style or due to repeated exposures to activating circumstances. Over time, excessive activation can lead to a reduced ability to adjust in the usual way to challenging circumstances with low hormone levels and weakened responses of tissue cells to the hormones. Several observations reveal altered SNS function in people with FMS/CFS, including poor blood flow responses when cold is applied to the hands, inadequate SNS activation in response to stress conditions such as exercise or noise, and failure to rapidly adjust blood pressure upon changing positions or posture, for example, from lying down to standing.

During threat of or actual emotional or physical challenge, besides activation of the SNS (seen in higher levels of epinephrine and norepinephrine), activation of the HPA axis involves the release of corticotropin-releasing hormone (CRH) from the brain hypothalamus, which affects the pituitary gland and its release of adrenocorticotropin hormone (cortisol release from the adrenal glands into the bloodstream). People with FMS can display low 24-hour blood levels of free cortisol, and a vigorous adrenocorticotrophic hormone (ACTH) but blunted cortisol response to injected CRH, indicating reduced responsiveness of the adrenal glands. In addition, patients with FMS can show low blood levels of growth hormone (GH), thyroid stimulating hormone, thyroid hormones (free T<sub>3</sub> and T<sub>4</sub>), and insulin-like growth factor-1. The vast majority of people with FMS

report sleep disturbances, which might be linked to at least some of the hormone changes. Their sleep has been observed as lighter and more fragmented in the early part of the night (e.g., the time when GH peaks), and people predominantly report waking up tired or unrefreshed from their sleep. Low levels of GH, among other hormones, are correlated to and perhaps instigate or are a consequence of sleep disturbances.

Both CRH and cortisol, as well as other hormones, have wide-ranging effects on emotions, thinking, and behaviors that resemble many of the clinical features of FMS. For example, in animals, CRH produces physiological and behavioral arousal behaviors that are in synchrony with the clinical picture seen in FMS—that is, reduced energy, tiredness, reactive mood, and weight gain. It has been argued that the low cortisol response and CRH pattern might explain overlap between FMS (and perhaps related conditions) and psychiatric illness. There is evidence that “melancholic” type major depression is manifested in CRH and cortisol elevations. However, “anergic” type depressive illness is manifested in reduced activity of the HPA axis and is associated with profound fatigue, bodily symptoms, and mood reactivity, similar to those in FMS. This latter pattern also is evident in the depressive phase of bipolar illness, seasonal affective disorder, and with primary low-thyroid conditions (Demitrack & Crofford, 1998).

Questions remain as to the role of inherent tendencies to autonomic nervous system and HPA disturbances versus acquired tendencies due to prolonged chronic stress exposure, reduced physical activity, and sleep/wake disruptions in the development or continuation of FMS/CFS. Furthermore, while disrupted SNS and low HPA responsiveness can potentially help explain fatigue and cognitive or emotional upset in FMS, it does not go far in explaining the exquisite pain sensitivity that people with FMS report.

In FMS, the point at which sensory input (e.g., touch pressure) becomes painful is lower than normal and pain tolerance is low. When pressure was applied to designated tender points, people with FMS displayed a steady linear rise in pain intensity ratings from the beginning as pressure was increased. In contrast, control subjects reported no pain over the first half of the pressure intensity application, followed by a rapid rise in reported pain after that point (Bendtsen, Norregaard, Jensen, & Olesen, 1997).

### Possible Explanations for Heightened Pain Sensitivity

Scientists are pursuing evidence for brain and nerve alterations that might explain heightened pain in the face of no obvious tissue injury as is evident in FMS. For example, blood flow to key areas of the brain involved in pain sensation is augmented in people with FMS compared to those without FMS. Evidence that chemicals active in pain transmission and modulation, both excitatory ones in excess or imbalanced against inhibitory ones, is being pursued. As reviewed by D. J. Clauw (1995), major excitatory chemicals that potentially heighten pain sensitivity include amino acids (building blocks of proteins) acting on cell membrane receptors (N-methyl-D-aspartate type). Another is Substance P, a chemical within nerve endings that facilitates pain nerve cell transmission in tissues, including spinal cord neurons (i.e., dorsal horn section known to be active in pain inputs), thereby promoting pain sensations. Pain nerve cell stimulation is countered or modulated in the spinal cord by inhibitory chemicals such as serotonin, norepinephrine, and opioids released from nerve cells higher in the brain. These act as natural analgesics and dampen pain sensations (Clauw, 1995). Serotonin reduces pain sensations and modulates the amount of Substance P available in tissues.

The amount of pain promoting Substance P varies in different tissues, but people with FMS show elevated levels of Substance P in spinal fluid but relatively normal levels in the bloodstream. As it turns out, blood contains high levels of substances (enzymes) that degrade Substance P, which may account for not seeing high levels in blood. However, these degrading substances are markedly lower in bladder, nose, and lung tissues, leading to the speculation that excess Substance P in these structures without high levels of breakdown enzymes could promote irritative symptoms such as irritable bladder, running nose (rhinitis), and hoarse throat (laryngitis), all symptoms prevalently associated with FMS.

As well, people with FMS exhibit low blood levels of pain-reducing serotonin and its breakdown product (5-hydroxyindoleacetic acid), and low spinal fluid levels of a building block for serotonin (tryptophan). However, serotonin levels have not been shown to correlate with pain and have been more predictive of depressed mood than pain, and paradoxically high levels are present in other painful conditions (Clauw, 1995).

Furthermore, the picture is more complicated in that other pain-related chemicals have also been implicated in FMS. For example, the pain-producing effects of Substance P might be potentiated through nerve growth factor, which is elevated in FMS patients (Giovengo, Russell, & Larson, 1996), as is calcitonin gene-related peptide. Nerve growth factor facilitates growth of Substance P-containing nerve cells and calcitonin gene-related peptide, which is in the same vicinity as Substance P in nerve cells, inhibits breakdown substances for Substance P. People with higher levels of these chemicals display more pain sensitivity. As more studies ensue, an even more complex picture of chemical imbalances no doubt will emerge.

Although the stress nervous and hormone systems and the pain biochemical lines of research mainly have occurred separately, emerging lines of investigation are connecting the two, based on how the stress and immune systems interact. For example, release of the stress hormones, norepinephrine and epinephrine, inhibit type 1/pro-inflammatory cell chemicals (called cytokines), such as interleukin (IL-12), tumor necrosis factor-alpha, IL-1, IL-8, and interferon-gamma by immune cells, whereas they stimulate the production of type 2/anti-inflammatory cytokines such as IL-10 and transforming growth factor-beta. Therefore, stress activation or the failure of normal stress activation can alter the immune balance of substances that promote or inhibit the inflammatory component of an overall systemic defense response. In patients with FM, increases in cytokines, for example, IL-8, which promote pain and whose release is stimulated by Substance P, have been observed over time. Much more study is necessary to fully outline the connection between stress and immune function.

## SUMMARIZING SPECULATIONS IN UNDERSTANDING FMS

Piecing together a comprehensive biobehavioral explanation for FMS remains elusive, but certain speculations are warranted. The set of lifestyle and behavioral contributing factors is likely to vary across individuals. Any full explanation will involve highly complex hormonal and cellular chemical interactions, involving much more than any one organ system but certainly the diffuse stress and immune systems. It is likely that some individuals have a genetic propensity to display a highly activated and/or unrelenting stress psychophysiological profile as they are exposed to

and have to cope with life challenges. Particularly vulnerable to ultimately manifest FMS are people who experience intense emotional life strain (e.g., abuse) and/or who are driven to high levels of intellectual and physical performance.

A heightened stress activation pattern incorporates the stress nervous system and stress hormones through alterations that involve imbalances of various inflammatory/immune defense cellular components within bodily tissues (e.g., cytokines), and within brain and spinal cord nerve tissues (e.g., neurotransmitters and neuromodulators). This engenders a heightened sensory sensitivity with a shift to experiencing pain upon exposure to previously nonpainful sensory input (pressure, movement) and a variety of other symptoms. While this stress-related emotional arousal and physiological activation pattern likely goes undetected over time, it could progressively intensify or worsen over time to a point where it eventually fails to be adequately or normally responsive to challenges, physical or emotional, perhaps due to prolonged stress exposure or inherent style coupled with reduced efficiencies in re-regulating components that come with aging. Thereby, an extraordinary challenge will result in (trigger) acute manifestations of FMS, followed by a lengthy recovery time during which manifestations might ebb and flow.

Clearly, FMS represents a condition in which personal styles, emotions, and behaviors are interlocked with bodily physical functions in ways that can lead to illness but in ways we do not yet fully understand enough to prevent or treat as adequately as we might. FMS, closely linked to CFS, is still a mystery—only to be solved through further multivariate studies.

## FIBROMYALGIA SYNDROME: COGNITIVE-BEHAVIORAL TREATMENT

Fibromyalgia syndrome (FMS) consists of a pervasive set of unexplained physical symptoms with generalized pain and hypersensitivity to palpation at specific body locations (tender points, or TPs; Wolfe et al., 1990; see Figure 1) as the cardinal features. In addition, patients report persistent fatigue, sleep disturbance, feelings of stiffness, depression, anxiety, cognitive impairment, and general malaise sometimes referred to as "fibro fog" (Baumstark & Buckelew, 1992). FMS may have an insidious onset without any identifiable cause, may develop following a flu-like illness, or may rapidly develop following a trauma such as a motor vehicle accident or emotional distress (Clauw & Chrousos, 1997; Turk, Okifuji, Starz, & Sinclair, 1996).

**Figure 1** Location of Tender Points

SOURCE: Okifuji, Turk, Sinclair, Starz, and Marcus (1997).

The population prevalence of FMS is estimated to range from .66% to 10.50% (Schochat, Croft, & Raspe, 1994). The variability in prevalence may result from differences in classification criteria since not all of these studies used the American College of Rheumatology criteria (Wolfe et al., 1990). Bennett (1995) estimated that approximately 5 million Americans have FMS. FMS is more commonly observed in women, with a female to male ratio of 7 to 1 in those seeking treatment. In community samples, however, the ratio is closer to 3 to 1, females to males.

## THE TORMENT OF FMS

Beyond the pain and related symptoms, health care providers or the legal system confronts FMS sufferers with a poorly understood disorder that is not well accepted. The lack of objective medical findings to confirm the diagnosis can result in confusion and frustration. Interpersonal relationships often suffer as the

impact of FMS extends beyond the physical to affect the emotional, occupational, social, and recreational areas. As symptoms affect more and more of the person's life, psychosocial and behavioral factors come to play an expanding role.

There is growing consensus that FMS reflects an abnormality in central processing of noxious sensations characterized by hypersensitivity to stimulation. In general, biopsychosocial models of pain have been proposed to integrate physical, psychosocial, and behavioral contributions to pain perception and adaptation (Turk & Sherman, 2002).

## GENERAL TREATMENT RECOMMENDATIONS

Although FMS has some unique characteristics, many of the traditional cognitive and behavioral interventions have been adapted for use. This entry describes the application of the cognitive-behavioral therapy (CBT) approach highlighting some of the specific features that are particularly important.

### Education

Information and reassurance are essential for treating FMS. The lack of a definitive explanation for the symptoms often produces fears that something serious, but as yet unidentified, is causing the symptoms; that the symptoms will become progressively worse; of being told that there is nothing that can be done; of being told that the problems are all caused by psychological factors (i.e., "imaginary and all in their heads"); and that they will be told to learn to live with symptoms without being told how. Consequently, it is essential that treatment begin with information about the nature of FMS, the possible causes, and the contributions of emotional, behavioral, and cognitive factors, as well as physical contributions.

Education includes a discussion of the distinction between acute pain and chronic pain. Acute pain is rightly seen as a signal of *harm* or potential damage or danger to the body. In the case of FMS, however, the pain is no longer a signal of damage to the body. Thus, it is important to make the distinction between *hurt* and *harm*. Patients are informed that they will be asked to increase physical activity and exercise. The clinician should acknowledge that a conditioning program will likely cause some increase in the level of pain as muscles become sore after months or years of disuse but that the exercises will cause no permanent damage.

### Focus on Function, not Cure

Patients with a rigid conviction that something is physically wrong and needs to be corrected can often obstruct treatment of FMS as it reinforces a passive role that will impede acceptance of self-management and subsequently progress toward improved physical and psychological functioning. If patient and therapist agree to embark on treatment, therapy should always focus on reduction of emotional distress, functional gains, and improvement in quality of life, rather than on complete elimination of symptoms and cure.

### Goal Setting

Clinicians should focus on goal setting as a means to direct behavior into achievable, reinforcing objectives. Goal setting achieves multiple purposes. First, people with FMS need to have realistic goals. If a patient enters treatment with the goal of being "pain free" and "just like I was before I developed FMS," then treatment should focus first on education about FMS, a discussion about how treatment for FMS involves making significant lifestyle changes, pacing resources, and maintaining these changes despite symptom flare-ups and remissions.

A second function of goal setting is to provide an evaluation of the concordance between the patients' expectations and those of their health care provider. Clinicians must ensure that treatment goals are mutually understood and acceptable. Lack of acceptance will undermine motivation and impede both progress and successful outcomes. Clinicians should emphasize a collaborative relationship. Together the therapist and clinicians should work to identify achievable goals that are measurable and within the patient's control.

### Relaxation

Relaxation is an integral part of the self-management program for FMS patients. There are many different methods to help patients learn to relax (e.g., controlled breathing, progressive muscle relaxation, autogenic training), no one of which is better than any other. Moreover, different people will find different methods more appealing. Thus, the therapist should work with patients to help them learn which methods can be most useful for the individual patient.

## Imagery

One of the most commonly used means of diverting attention from symptoms is focusing attention on events external to sensations. Clinicians may teach imagery as a strategy that patients may use when they are feeling overwhelmed by their symptoms and distressing aspects of their lives.

The clinician should inform patients that the use of imagery, as well as relaxation, will become easier with practice, just like any other skill. The clinician teaches the patient to include all senses to enhance the vividness of images. The clinician should attempt to create a “no lose” situation by emphasizing that there are many types of images and the clinician will work with patients to find one that might be helpful. The idea is to help patients develop a repertoire of coping strategies that they can use on their own. A nonjudgmental attitude should be encouraged as the patient attempts to identify methods that can be of assistance.

## Pacing and Increasing Activities

FMS patients often anticipate that physical activity will cause pain and further damage. Consequently, they avoid activities for fear they will make themselves worse (Vlaeyen et al., 1997). This may lead to avoidance of activity to prevent more pain, fatigue, and injury. Treatment should focus on breaking the association between activity and anticipated pain by encouraging patients to gradually increase the pace of their activity. Patients are encouraged to understand that through their efforts, they will increase the level of endurance and reduce fatigue.

A pacing exercise calls for patients to establish a daily time quota for a particular activity, and to spend only the preset amount of time on the activity. Patients are asked to perform the activity for several days, up to the point where they are beginning to feel pain, fatigue, or any other sign that they have reached their limit. Using this as a baseline, the therapist helps the patient to create a manageable activity plan, with gradually increasing activity levels that patients are likely to be able to maintain.

## Sleep

A common symptom reported by FMS patients is poor sleep. The clinician should encourage patients to establish a sleep hygiene plan that consists of: a standard wake-up time, getting out of bed during extended

periods of being awake, avoiding sleep-incompatible behaviors in the bed, eliminating daytime napping, and avoiding activities and foods (e.g., caffeine, alcohol) consumed near bedtime that might interfere with sleep.

## Cognitive Dysfunction

Many patients with FMS report difficulty concentrating, attending to new material, and less frequently, difficulty with short-term and long-term memory (Glass & Park, 2001). The attention and concentration deficits may be more related to sleep deficits, medication, physical deconditioning, and depression than to FMS itself (Landro, Stiles, & Sletvold, 1997). Perceived memory deficits reported by FMS patients are often disproportionately greater than their objective deficits determined by cognitive testing (Grace et al., 1999).

## Maladaptive Thoughts

Many people with FMS subscribe to a number of negative and maladaptive thoughts about themselves and their plight. Clinicians should directly address the relationship between thoughts, feelings, behavior, and physiology. To assist in the discovery process, patients may be asked to complete a diary recording when their symptoms are worse, what they were doing, what they were thinking, how they felt, and how their thoughts and feelings affected what they did.

Clinicians may use an *ABCD* model to help the patient identify and alter maladaptive thoughts and behaviors: *activating* event or stressor, *belief* system (thoughts and attitudes) about the stressful event, *consequences* of the activating event (feelings) and a way to change the above sequence of events, and *disputing* the negative thinking discovered in *b*, which can affect how badly people feel in *c*.

## Stress

Many patients with FMS fail to see the relationship between stress and their physical health. Clinicians should assist patients to identify stressors and distinguish between stressors they can or cannot control. Emphasis can be placed on modifying the stressors that patients can control and practicing other skills such as relaxation, time management, and effective communication for those stressors that they cannot control.

**Table 1** Subgroups of Chronic Pain Patients Based on the Multidimensional Pain Inventory Relative to Other Chronic Pain Patients*Dysfunctional patients report*

- Higher levels of pain
- Higher levels of perceived interference of pain with their lives
- Higher levels of emotional distress
- Lower levels of perceived control over their lives
- Lower levels of activity

*Interpersonally distressed patients report*

- Lower levels of perceived support
- Higher levels of negative (punishing) responses from significant others
- Lower levels of solicitous responses from significant others
- Lower levels of distracting responses from significant others

*Adaptive copers patients report*

- Lower levels of pain (although still seeking treatment)
- Lower levels of perceived interference of pain with their lives
- Lower levels of emotional distress
- Higher levels of perceived control over their lives
- Higher levels of activity

SOURCE: Turk and Rudy (1988).

## Relapse

FMS is a chronic condition and symptoms will fluctuate between relative reductions in symptoms and flare-ups, hence the emphasis on pacing noted previously. As a consequence, a relapse prevention model is important. Clinicians should present this as a process where people can find themselves relapsing and need to reinstitute their self-management plan. They acknowledge that there will be good and bad days as everyone experiences “ups and downs.” The key to consistent recovery is not the absence of symptoms but the willingness to reenter the process of recovery with independent action even after a flare-up.

The challenge for patients is twofold, first, to recognize when they are relapsing and second to return to the use of their self-management skills. Patients can be asked to list the behaviors, thoughts, and feelings that act as cues or predictors that a relapse is likely to occur. They are then asked to list the behaviors that have helped in the past and to develop a written plan for engaging in those behaviors. Patients can be encouraged to think of factors that might contribute to flare-ups and to identify and anticipate *high-risk* circumstances. If they can identify some, they can attempt to alter them, avoid them, plan on how to respond to them, or accept them as inevitable and plan how they will accommodate their activities when flare-ups do occur.

## PATIENT HETEROGENEITY

A number of investigators have suggested that FMS patients are not a homogeneous group. Turk and Flor (1989) suggested that FMS might consist of several patient subgroups with different constellations of physical and psychological features. They argued that delineation of the relevant subgroups would facilitate the identification of the mechanisms underlying the symptoms of FMS and the development of treatments customized to address specific needs of different patient groups.

Turk and Rudy (1988) developed an empirically derived taxonomy of chronic pain patients based on patients' responses to the West Haven-Yale Multidimensional Pain Inventory (MPI; Kerns, Turk, & Rudy, 1985)—dysfunctional (DYS), interpersonally distressed (ID), and adaptive copers (AC) (see Table 1).

Turk, Okifuji, Sinclair, and Starz (1996) found that the majority of FMS patients (87%) can be classified into one of the three primary groups: *DYS*, *ID*, and *AC*, with approximately one third classified in each group. The distinct characteristics associated with each patient subgroup suggest that prescription of a uniform intervention for all patients might result in less than optimal outcomes since the specific needs of some patients will not be directly addressed. It may

be more appropriate to customize treatment to meet their specific clinical needs (Turk, 1990). For example, although the patients in both DYS and ID groups were depressed, depression in the latter group may be closely related to marital and interpersonal problems. Meaningful improvement, therefore, may not be achieved without addressing interpersonal or marital issues for ID FMS patients. Being able to prescribe specific treatments based on patient characteristics, rather than the more typical "one size fits all" approach, is likely to benefit a greater number of patients and ultimately to be more cost-effective. The clinical value of customizing treatment to the three subgroups identified has recently been demonstrated in several studies (Strategier, Chwalisz, Altmaier, Russell, & Lehmann, 1997; Talo, Forssell, Heikkonen, & Puukka, 2001; Turk, Rudy, Kubinski, Zaki, & Greco, 1996).

### Interpersonal Problems

A significant number of patients with FMS fit the ID profile on the MPI (Turk, Okifuji, Sinclair, & Starz, 1996). People with such profiles show high levels of pain and depression and report low social support or high levels of negative or punishing responses from significant others. For these people, treatment needs to include effective communication skills to facilitate cooperation with others. This is a fairly unique group, and little attention has been given to helping them address problems associated with interpersonal relationships.

Role-playing may be used to help ID patients learn more effective means of communication and interpersonal problem solving. Assertiveness training is particularly important for assisting people in making their different attitudes and behaviors actually work in their interpersonal contexts. For example, as one shifts from an attitude of feeling responsible for everything to a perspective that allows for acknowledgment of limits and asking for help, she or he may need to learn new communication skills to facilitate cooperation from others, including family and friends.

Partner or family counseling may be appropriate for ID patients. Significant others (e.g., spouses, other family members, partners) can be taught how they can be most helpful to the affected person, whether through instrumental, direct problem-solving support, or through emotional support and validation of the person's experience and efforts.

### CONCLUDING COMMENTS

Preliminary studies using a CBT approach have been generally positive in reducing symptoms and related distress, but not in eliminating all symptoms of FMS (e.g., Nielson, Walker, & McCain, 1992; Turk, Okifuji, Sinclair, & Starz, 1998; Turk, Okifuji, Starz, & Sinclair, 1998). Larger-scale studies with appropriate control groups and adequate follow-up periods are required to confirm the effectiveness of CBT. Research is needed to determine what set of FMS patients, with what characteristics, can benefit from generic CBT combined with activity therapy. The failure of many patients to achieve and maintain positive outcomes indicates, most assuredly, that one size does not fit all.

## 5 A DAY—FOR BETTER HEALTH! PROGRAM

---

The 5 a Day—for Better Health! Program is a large-scale national public/private partnership health promotion program that encourages all Americans to increase their fruit and vegetable intake to 5 to 9 servings daily for good health. The program seeks to achieve broad environmental change as well as individual behavior change by using a comprehensive mix

of multidimensional (physical, social, behavioral, and spiritual) strategies to achieve and sustain impact. The program emphasizes working through multilevel (national, regional, and community) health and industry organizations to positively affect the entire nation's fruit and vegetable intake, resulting in a large public health impact.

#### DIET-DISEASE LINK

A high intake of fruits and vegetables decreases the risk of certain types of cancer, cardiovascular disease, and other chronic diseases. In fact, diets high in fruits and vegetables (including at least 5 servings daily) alone may prevent 20% or more of all new cases of cancer worldwide (World Cancer Research Fund, American Institute for Cancer Research, 1997). Similarly, diets high in fruits and vegetables are associated with a decreased risk of coronary artery disease and stroke. Emerging research suggests a role for fruits and vegetables in reducing the risk of obesity and diabetes.

The evidence that a variety of fruits and vegetables may contribute to the prevention of cancer, heart disease, and other chronic diseases is drawn from hundreds of population and laboratory studies. Fruits and vegetables are sources of vitamins and minerals, carotenoids and other antioxidants, and various phytochemicals that separately or in combination, affect plausible biological mechanisms for reducing the risk of chronic diseases. The overwhelming weight of the evidence has led to a major focus on fruit and vegetable consumption in U.S. federal nutrition policy and educational/behavior change initiatives.

#### 5 A DAY—FOR BETTER HEALTH! PROGRAM STRUCTURE

The national 5 a Day—for Better Health! Program objectives include (1) increasing public awareness of the need to consume at least 5 servings of fruits and vegetables and (2) providing consumers with specific information on how to include more fruits and vegetables into their daily eating patterns. The use of a trademarked logo (see Figure 1) and a licensing process to obtain formal commitment is unique to the 5 a Day program and has been essential in conducting a program of this magnitude. The legal documents provide the basic rules and an unwavering framework from which each partner can create its own signature 5 a Day program.

**Figure 1** 5 a Day Trademarked Logo

All licensed participants use the logo to identify their affiliation with the national 5 a Day program.

The National Cancer Institute (NCI), after funding the initial state-based California 5 a Day program, initiated the national 5 a Day program in 1991 as a large-scale, public/private partnership with the Produce for Better Health Foundation (PBH) to reduce the risk of cancer and other diseases in the United States. PBH, a nonprofit nutrition education foundation representing the fruit and vegetable industry, has licensed approximately 1,000 industry members, including retailers, growers, shippers, packagers, merchandisers, commodity boards, trade associations, and producers of branded products, to conduct 5 a Day efforts at the community level. The retailers represent more than 30,000 supermarkets across the country. NCI has licensed all 50 state health departments, the health promotion programs of the uniformed services, and the Indian Health Service to develop 5 a Day health promotion programs.

The program was founded on the idea of a collaborative promotion by the entire fruit and vegetable industry, with scientific and intervention support from the government health partners. Since 1991, the partnership has grown to include many state and national government agencies with an interest in dietary behavior change, such as the Centers for Disease Control and Prevention (CDC), the U.S. Department of Agriculture (USDA), and nongovernment health organizations, such as the American Cancer Society (ACS). The organizational structure of the multilevel,

public/private partnership is one in which public and private sectors work together at the national, state, and local levels through a variety of intervention channels.

Internationally, the 5 a Day program public/private partnership model has been applied in several countries, including Australia, Canada, Denmark, Germany, Hungary, the Netherlands, New Zealand, Norway, and Sweden. Key elements identified for successful programming include strong public/private partnerships; evidence-based governmental nutrition policy; a simple, actionable message; a clearly defined target audience; and a plan for program evaluation.

### LINKING THEORY, RESEARCH, AND PRACTICE

From the inception of the program, current theories of behavioral change have been incorporated into program planning. Theory-driven community-based behavioral change and communication research projects were funded and carried out, and more recently, plans for wide-scale dissemination of evidence-based practice are being instituted. This feedback of continuous theoretical and research evidence strengthens and invigorates the program.

The main behavioral theories that were selected to guide the national 5 a Day program were the health belief model, with a focus on a person's perception of a health threat and the assessment of recommended behaviors for prevention (Janz & Becker, 1984); social cognitive theory, which proposes that behavior is explained by a dynamic reciprocal theory whereby personal factors, environmental influences, and behavior continually interact (Bandura, 1977, 1986); and the transtheoretical or stages of change model, which addresses an individual's readiness or attempt to change toward healthy behaviors (Prochaska, DiClemente, & Norcross, 1992). Theoretical constructs were incorporated into the guidelines for all licensed program participants, and a strong theoretical design is a crucial aspect of all 5 a Day-related behavioral change research and interventions.

### PROGRAM COMPONENTS

Message and behavioral change activities are disseminated through four main program components: media and communications, industry initiatives/point-of-sale interventions, community-level programs, and research and evaluation efforts. Using social marketing

techniques and theory-based strategies, the 5 a Day program partners work individually and collaboratively to develop, implement, and evaluate a variety of interventions.

### Mass Media and Communications

Mass media (newspapers, magazines, television, radio, and the Internet) reach large segments of the population and provide opportunities to deliver messages that encourage behavior change. The 5 a Day communications component uses an audience segmentation, social marketing approach based on the consumer-based health communications (CHC) model (Lefebvre et al., 1995). The stages of change theory was employed to help the program assist consumers in moving along the behavior change continuum from creating awareness of the need to eat 5 or more servings of fruits and vegetables, to providing skill-building tips for preparing to make a change in eating behavior, to eating more fruits and vegetables.

The sequence of strategies to shape the media campaign included initial planning using the CHC model, and formative research to determine the target audience and core messages. The 1991 baseline nationally representative telephone survey of 2,800 adults revealed that most respondents were eating approximately 3.4 servings of fruits and vegetables (not including French-fried potatoes), with one out of five eating fewer than 2 servings daily. The survey also found that only 8% of Americans were aware of the need to eat at least 5 servings of fruits and vegetables for good health. This information served as the cornerstone for the national media launch. Focus group research and market research data defined the target media audience as "adults, currently eating about three servings or less of vegetables and fruits and trying to consume more." The core message strategy for this target audience was to increase self-efficacy and skills by teaching the target audience how to "add two or more servings of vegetables and fruits a day 'the easy way' instead of making it hard."

With an NCI annual media budget range of \$1-\$1.5 million during the first 10 years of the program, a presence in paid media was not possible. However, with the advantage of the NCI imprimatur, the decision was made early to deliver messages through unpaid media placements and to devise strategies that would ensure sufficient media penetration. The strategy of focused messages, repeated often and consistently,

with new and updated approaches to keep the target audience interested and engaged, was employed. The program used a variety of media approaches to reach the broadest audience possible with limited resources. Multiple media vehicles have included news columns and magazine articles to television and radio programming and Web sites. An additional resource of media placement by state and local health partners multiplied the message penetration and helped in tailoring the message for diverse audiences. Some of the themes and graphics used for National 5 a Day Week have reflected findings from consumer research. For example, “The Original Fast Food” theme and graphic were created to emphasize the ease and convenience that fruits and vegetables offer to the busy target audience, who want to eat healthfully but have little time to plan. The “Sample the Spectrum” theme and graphic translate emerging science on phytochemicals in an easily understood way to the public and encourage Americans to consume 5 to 9 daily servings of colorful fruits and vegetables.

Tracking and evaluation are consistently conducted throughout the media campaign to track progress, redirect strategies, and fine-tune tactics. Tracking and evaluation projects include media content analysis, omnibus surveys to track awareness, research audits, and target audience analysis. Omnibus awareness surveys have shown that awareness of the 5 a Day message increased from 22% in 1992 to 35% in 1999.

In the first decade of the national program, the media campaign targeted the general adult population. Given today’s awareness of the needs of the medically underserved populations, the 5 a Day program is redirecting its communications focus to target those populations with a disproportionate incidence of cancer and other chronic diseases. For example, the 2002–2003 communications strategy focuses on African American males, whose cancer rates are disproportionately greater than other demographic groups.

### **Produce Industry Initiatives/Point-of-Sale Initiatives**

A strong point of the national 5 a Day program is the unique partnership between the fruit and vegetable industry and the public health community, whereby all benefit from increased sale and consumption of fruits and vegetables. The overwhelming value of the produce industry to the public health community is realized in marketing dollars and a viable point-of-sale

venue whereby all Americans can be reached with the 5 a Day message. The industry benefits from the scientific credibility and public health infrastructure that government health agencies bring to the partnership.

The use of supermarkets’ marketing power is a powerful way to reach consumers through ads, circulars, and in-store interactive educational activities. The majority of the large U.S. supermarket chains are licensed and active partners of the program. Most supermarkets provide 5 a Day signage and educational materials, include the logo with health messages in newspaper advertising, and conduct promotional activities throughout the year. As an example, the largest wholesale food distributor (more than 5,000 stores) conducts a yearly 5 a Day merchandising contest among its stores. Stores participating in the contest increased their sales as a result of the displays and activities. Another large chain conducts a twice-yearly elementary school children’s 5 a Day and Physical Activity promotion in all of their stores. Each store “adopts” a school and provides funding for health promotion events.

Noncommercial food service, that is, school and worksite cafeterias and other noncommercial venues, have worked extensively with public health partners to change the food service environment to be more supportive of fruit and vegetable consumption. Many schools have instituted salad bars and increased produce availability in school breakfast and lunch.

### **State and Community Programs**

The state and community 5 a Day programs primarily function under the leadership of coordinators in each of the 50 state health departments, using existing public health nutrition funding and voluntary industry in-kind support. Most states have developed coalitions comprising representation from the public and private sectors. Coalition members include state and regional representatives of the national-level steering committee members, such as state departments of agriculture, cooperative extension services, and ACS regional offices; state departments of education; voluntary agencies; hospitals and cancer centers; licensed 5 a Day industry participants; and others. Collaboration among partners helps to reach consumers more effectively, maximize the use of scarce resources, coordinate state and national media efforts, encourage innovations, and create working relationships between the public and private sectors.

Schools, worksites, and supermarkets are commonly used intervention channels for disseminating 5 a Day activities. A major effort is currently being expended to identify funding sources for 5 a Day state and community interventions, as part of ongoing activities or new initiatives.

### Research, Dissemination, and Evaluation

Research and evaluation are integral components of the program, and essential for long-term success. The NCI, USDA, CDC, ACS, PBH, and other national organizations fund research projects in communications, program evaluation, and nutrition and behavioral change to increase fruit and vegetable consumption. Efforts to disseminate the evidence-based strategies from these and other studies to practitioners throughout the 5 a Day infrastructure are a priority.

The cornerstone of 5 a Day research is the set of nine community-based research studies with randomized designs funded in 1993-1997 by the NCI to implement and evaluate interventions aimed at increasing fruit and vegetable consumption among specific population segments in specific community settings. The intervention channels and populations were schools, worksites, food assistance programs, and churches targeting African Americans, Hispanics, people with low income, children, and others. Across the studies, statistically significant positive changes in fruit and vegetable consumption ranged from 0.20 to 1.68 servings per day, with an average effect size of 0.68 servings per day. These studies were successfully implemented and substantially increased understanding of how to motivate healthful eating behaviors in a variety of settings and in diverse populations.

Evaluation research focused on the national 1991 baseline and 1997 follow-up surveys to measure fruit and vegetable consumption and the corresponding psychosocial factors. In addition, a process evaluation was performed to document programmatic growth and activities at the state and local levels. The difference between the baseline and follow-up surveys showed an overall modest increase of 0.23 servings of fruit and vegetable consumption from 1991 to 1997. However, the 1997 estimated mean fruit and vegetable intake of approximately 4 servings in the adult U.S. population is still a full serving short of the minimum 5 a Day goal. This same survey showed a significant ( $p < .05$ ) increase in those consuming 5 or more servings

daily (23-27%), and a significant increase in those aware of the 5 a Day message (7-20%).

### SUMMARY

The multifaceted 5 a Day—for Better Health! Program has grown to be the largest public/private partnership public health nutrition and behavior change program in the world. Over the first decade of the 5 a Day program, the following have occurred: (1) Fruit and vegetable consumption has shown a positive trend; (2) awareness of the 5 a Day message increased significantly; (3) state 5 a Day coalition infrastructures are in place and are composed of a variety of members from public and private sectors; (4) efforts to expand to a national steering committee leadership are well under way; and (5) research shows that changing fruit and vegetable consumption behavior is possible.

## FRAMINGHAM HEART STUDY

---

The Framingham Heart Study is the oldest and perhaps best-known population study in the United States. In 1948, a group of medical researchers entered the New England town of Framingham, Massachusetts (population about 68,000), to begin one of the largest and most important epidemiological studies in the history of medicine. Framingham is an average Massachusetts town, not far from Boston. In fact, it is along the course of the Boston Marathon.

The purpose of the Framingham Heart Study was to determine the causes of stroke and heart failure. Before the Framingham study, most investigations of heart disease had been retrospective. Retrospective studies start with a group of people who have already developed heart trouble and then look into their pasts to determine what they had in common. In contrast, the researchers in the Framingham study started with healthy people and attempted to predict which ones would eventually die of heart and circulatory problems. This approach is called prospective and is considered to produce superior and more convincing

scientific data than the retrospective method. The study began by identifying every other man and woman in Framingham between the ages of 30 and 60 who had no signs of heart disease. In the beginning there were 5,127 participants. Each time a new subject was enrolled, he or she was given a thorough physical exam and a detailed interview about lifestyle. The subjects were remeasured every 2 years.

Numerous findings from the Framingham Heart Study have influenced medicine and public health. For example, in 1960, investigators from the Framingham project reported that cigarette smoking increased the risk for heart disease. Prior to that, most attention had been focused on the relationship between tobacco use and cancer. In 1961 results from the Framingham study were among the first to demonstrate that elevated levels of cholesterol, blood pressure, and abnormalities in electrocardiograms were associated with the risk of heart disease. By 1997, the Framingham study demonstrated that physical activity and exercise reduced the risk of heart disease and that obesity increased the risk of heart disease. The Framingham study evaluates other health outcomes in addition to heart disease. In 1970, data from the study convincingly demonstrated that elevated blood pressure increases risk of stroke. In 1976, a report from the Framingham study was among the first to clearly document that the risk of heart disease in women increases at the time of the menopause.

By 1988, the study had demonstrated that not all levels of cholesterol are the same. High-density lipoprotein (HDL) cholesterol was found to be a particularly important protective factor. As the study progressed, more sophisticated methodologies were employed. For example, evaluations of enlargement of the left ventricle, which is one of the two lower chambers of the heart, was shown to increase the risk of stroke in a 1994 publication from the Framingham study. In 1996, data from the study was used to demonstrate how high blood pressure progresses toward heart failure.

The Framingham Heart Study is now used to study many different chronic diseases. For example, there have been significant publications on diabetes, dementia, arthritis, and other problems. In addition, the study has been used to evaluate new risk factors for heart disease. For example, in 1990 the study demonstrated that homocysteine (an amino acid) may be an important risk factor for heart disease.

The Framingham Heart Study has also produced many findings relevant to psychosocial outcomes. The

Framingham study was among the first to demonstrate relationships between personality factors, including Type A behavior and heart disease in a 1978 publication. Clearly, some predictors of heart disease are beyond the subject's control, such as age (older people are more prone), sex (males are more prone), certain diseases such as diabetes, and race (Blacks are more prone). However, a major finding of the study was that some of the best predictors of heart disease and early death are direct consequences of behavior. These predictors of heart disease include smoking, obesity, high cholesterol level (perhaps associated with a high animal fat diet), physical inactivity, and possibly excessive tension and stress.

The Framingham Heart Study has been very important in establishing that some risk factors for heart disease are mutable, or subject to change. Thus, much of the current practice of preventive medicine was launched. Risk factors were identified, and important recommendations for behavior change were offered. The Framingham Heart Study has continued to follow the original group of participants. After more than 50 years, the study continues to contribute scientific insights. In addition, the study has been expanded to include the offspring of the original participants and, more recently, their grandchildren.

In summary, the Framingham Heart Study is one of the most significant epidemiological studies ever conducted. The study is funded by the National Heart, Lung, and Blood Institute and is expected to be an important contributor to our understanding of chronic disease for years to come.

## FUNDAMENTAL SOCIAL CAUSES OF DISEASE AND MORTALITY

---

The primacy of social conditions as determinants of health has been observed for centuries. In the 19th century, Virchow (1848) declared that “medicine is a social science.” Today, social epidemiologists articulate the centrality of “upstream causes” of disease and death. The concept of fundamental social causes adds to these statements the idea that explanations for the influence of social conditions on health cannot be reduced to the mechanisms that happen to link the two at any particular place or time.

To argue that social conditions are irreducible fundamental causes is more than an intellectual issue concerning the proper understanding of the role of social conditions in health. This argument also implies that policy seeking to ameliorate health disparities *must* address the social conditions that produce them. Addressing only the mechanisms will reliably fail to address health disparities.

This entry uses socioeconomic status (SES) to exemplify the theory of fundamental causes. A strong association exists between indicators of SES (education, occupation, and income) and mortality (Antonovsky, 1967; Sorlie, Backlund, & Keller, 1995). Clearly, biological mechanisms are involved in the SES-disease association. Just as clearly, other mechanisms must be involved—disease does not seep directly from income, educational, or occupational statuses into the body. Nevertheless, this entry argues that the effect of SES on mortality cannot be eliminated by addressing the mechanisms that link the two at any particular time. In this regard, one of the most striking features of the SES-health association is its persistence across time and place. It was present in the early 19th century in Mulhouse, France, in Rhode Island in 1865, and in Chicago in the 1930s (see Antonovsky, 1967) and is present in Europe and the United States today (Kunst et al., 1998; Lantz et al., 1998; Sorlie et al., 1995). Considering the vast differences in life expectancy, risk factors, diseases, and health care systems characterizing these different places and times, the persistence of the SES-mortality association is remarkable. Indeed, it is this persistence that suggests the irreducible nature of SES as a fundamental cause.

To proceed with our reasoning, imagine a causal model with SES as the distal factor linked to death by more proximal risk factors. If the proximal risk factors are eliminated, we would expect the SES-mortality association to be eliminated also. On the contrary, we have seen important instances in which major proximal risk factors were eliminated while SES disparities in mortality persisted. In the 19th century, overcrowding, poor sanitation, and widespread infectious diseases such as diphtheria, measles, typhoid fever, tuberculosis, and syphilis appeared to explain higher mortality rates among less advantaged persons. But the virtual elimination of those conditions and diseases in developed countries did not diminish SES inequalities in mortality (Rosen, 1979). In the 20th century, national health programs, providing free

medical care to all citizens, were instituted with the express purpose of radically diminishing another mechanism understood to be an important link between SES and health—differential access to health care. Again, SES disparities in mortality remain undiminished decades after these programs were adopted (Black et al., 1982). In both cases, mechanisms “explaining” the SES-mortality association were dramatically modified, independent of SES. Our causal-model approach would predict a substantial reduction in the association between SES and mortality, but this did not happen.

A ready answer to this puzzle is that the previous mediating risk factors have been replaced by others, such as health behaviors and psychosocial stress (Adler et al., 1994). This situation calls to mind Lieberman’s (1985) description of “basic causes,” which have enduring effects on a dependent variable because, when the effect of one mechanism declines, others emerge or become more prominent. House and colleagues first suggested that such a process might explain the enduring SES-mortality association (House et al., 1990). Lieberman’s notion of basic causes provides a critical insight for understanding the tenacity of the SES-mortality association, but it does not tell us what it is about SES that allows it to reproduce its effects despite the elimination of intervening mechanisms.

Link and Phelan (1995) argued that new mechanisms arise because higher-SES persons enjoy a wide range of resources, including money, knowledge, prestige, power, and beneficial social connections, that can be used to one’s health advantage. These resources directly shape individual health behaviors by influencing whether people know about, have access to, and can afford to engage in health-enhancing behaviors. Resources also shape access to contexts such as neighborhoods, occupations, and social networks that dramatically vary in their profiles of risk and protective factors. Thus, the processes implied by the fundamental-cause perspective operate at both individual and contextual levels.

This background allows us to specify the essential components of a fundamental cause of morbidity and mortality: First, it influences multiple disease outcomes. Second, it operates through multiple risk factors. Third, the association between the fundamental cause and mortality is reproduced over time via the replacement of intervening mechanisms. Finally, the “essential feature of fundamental social causes is that

they involve access to resources that can be used to avoid risks or to minimize the consequences of disease once it occurs” (Link & Phelan, 1995, p. 87). Because of the general nature of these resources, they are adaptable to changing health-related conditions and can be used to protect health no matter what the current risks, treatments, or diseases are.

## EVIDENCE

The first two propositions are strongly supported by existing data. Low SES has been related to numerous risk factors for disease and death, for example, smoking, sedentarism, being overweight, and excessive alcohol consumption (Lantz et al., 1998); stressful life conditions and social isolation (House & Williams, 2000; Turner, Wheaton, & Lloyd, 1995); preventive health care (Link et al., 1998); crowded, unsanitary living conditions; and malnutrition (Rosen, 1979). Low SES is also related to a multiplicity of diseases and other causes of death. For example, low SES is related to each of the 14 major causes of death in the International Classification of Diseases (Illikey & Mullen, 1985).

The third proposition is that the SES-morbidity/mortality association is reproduced through the replacement of mechanisms. Consonant with this proposition, historical evidence shows a consistently strong SES gradient in mortality since the 18th century (Antonovsky, 1967) concomitant with dramatic changes in the risk factors linking SES and mortality over this time. Moreover, there are important instances in which SES gradients in specific risk factors and disease outcomes have changed as predicted by the theory. When knowledge emerged about the benefits of a low-fat diet, higher-SES groups altered their diets more than did lower-SES groups (Popkin, Siega-Riz, & Haines, 1996). Similarly, as knowledge about the risks of smoking emerged, higher-SES people were more likely to stop or not start smoking (Pierce et al., 1989). Concomitant with these changes, the association of SES to coronary heart disease shifted from a direct to an inverse association (Beaglehole, 1990). Also, whereas lung cancer mortality was not related to SES as late as 1930, a large inverse association began to emerge in the 1950s (Logan, 1982). Until recently, breast cancer mortality was higher among higher-SES women, due to higher incidence in that group. But with better identification and treatment, the formerly positive association has

diminished, at least among White women, to near no difference (Heck et al., 1997).

More systematic analysis is needed to ensure that these examples are not a biased set of cases that happen to support the theory. Nevertheless, this evidence is supportive of the dynamic aspect of fundamental-cause theory—as knowledge about risk and protective factors changes, so do SES patterns of disease and death.

The fourth proposition concerns what we regard as the key feature of fundamental social causes: differential access to and utilization of resources. This proposition can be tested by identifying situations in which it is difficult to use resources to prolong life—when even the richest or most powerful person on earth cannot use those resources to escape death. If the utilization of resources is critical in prolonging life, then, when resources associated with higher status are useless, high SES should confer no advantage, and the usually robust SES-mortality association should be reduced. One such situation occurs when the causes and cures of fatal diseases are unknown: Socioeconomic resources cannot extend life, because we do not know how to direct those resources. A second situation occurs in old age. Death eventually comes to us all; thus, there must come a point when no amount of money, power, or other resources can overcome the biological imperative of death. Phelan et al. (1999) tested these predictions using the National Longitudinal Mortality Study and reliable ratings they developed of the preventability of death from specific causes. Consistent with predictions derived from the theory, Phelan et al. (1999) found that the SES-mortality association is much stronger for highly preventable causes than for less preventable causes and that the SES-mortality association weakens in old age when eventually no interventions can maintain life.

## CONCLUSION

The theory of fundamental social causes finds substantial support in broad historical facts and from the tests to which we have subjected it. This evidence increases our confidence in the validity of the theory. Nevertheless, the idea needs further tests that might be achieved through systematic observation of associations between SES and specific diseases over time as we learn more about those diseases. To the extent that the theory is correct and the effect of social conditions

on health is irreducible, the amelioration of health disparities must attend to the social conditions that so reliably produce them.

—Jo C. Phelan and Bruce G. Link

## GASTRIC ULCERS AND STRESS

---

Two major loci of ulcers in the upper gastrointestinal tract are the body of the stomach (gastric ulcers) and the duodenum. This entry focuses on gastric ulcers because peptic/duodenal ulcers are dealt with elsewhere in this encyclopedia. Physiological injury to the stomach ranges from irritations of the mucosal lining (petechiae) to erosions into the stomach lining causing surface bleeding (ulcerations) to lesions that penetrate the stomach wall (perforating ulcers).

Gastric ulcers became a common medical problem in the 20th century. Ulcers are not only painful but can be life threatening. Taken together, all the medications to treat ulcers are currently the world's best-selling and most profitable drugs.

Gastric ulcers have been considered typical psychosomatic disorders. Psychiatric thought from the 1930s attributed gastrointestinal disorders to intrapsychic conflicts often arising in highly motivated individuals frustrated by business world challenges. An alternative view that stress could cause physical illness arose primarily from the researches of Hans Selye on the body's physiological responses to "stress." He also argued that sources of stress could be psychological as well as physical. In dealing with this topic, we need to be clear about the key concepts. These include what we mean by *stress*, *psychosomatic*, and *disorder*.

*Stress.* Stress is discussed elsewhere in this encyclopedia in some detail. The definition of *stress* is not simple, but a reasonable working definition would be

chronic environmental strain and challenges, physiological and/or psychological, that threaten the organism's integrity.

*Psychosomatic.* The term *psychosomatic* implies an ancient mind-body "dualism" that is generally no longer accepted. We now know that our emotions and thoughts are emergent properties of brain function just as are other bodily processes. Nonetheless, the term psychosomatic persists as we try to distinguish the sources of the stress and when we wish to distinguish sources or processes that are clearly biophysical in origin from those that are psychological/emotional reactions to events, threats, or failures to cope with *either* the biophysical or psychological strain.

*Disorder.* Gastric problems range from indigestion to changes in gastric function (e.g., abnormal motility, increased acid production) to erosions in the stomach wall to lesions penetrating the stomach wall. Both erosions and lesions we shall call ulcers because they are on a continuum of severity. The disorder may include bacterial infection that exacerbates the erosions and may even cause stomach cancer. The issue of infection has become one of importance because recent medical practice has been to assume that all ulcers are the product of a bacterial infection (*Helicobacter pylori*) and hence a simple biophysical disease not involving causal or contributory psychological/emotional factors. Recently, this view has been undergoing revision toward one of ulcer being a stress-diathesis product, wherein stress interacts with other factors that may include genetics, bacteria, and lifestyle contributors such as smoking, alcohol use,

aspirin use, excessive exertion, irregular meals, and irregular sleep patterns.

Treatment for a disorder is often most effective if selectively targeted. To target a treatment, one may be aided by knowing the causal factors: physiological, psychological, or behavioral. Therefore, substantial research has been devoted to determining the causal variables and processes for gastric ulcers including the role, if any, for stress.

## BASIC PSYCHOLOGICAL SCIENCE AND THE STRESS-CAUSED ULCER ISSUE

We are all well aware of Ivan Pavlov's classic experiments on the conditioned reflex in which he used a metronome to signal impending food. We often overlook that he specifically demonstrated that components of the gut are sensitive to environmental relations that result in learning. Research since then has confirmed that most psychobiological and emotional responses are sensitive to the environmental relations that produce learning and come to occur as anticipatory responses. Stewart Wolf and Harold G. Wolff directly observed that a human patient's stomach responses are exquisitely sensitive to the individual's emotional state.

Psychological and medical sciences seek to understand complex health problems by developing animal models of the disorder because one can study their causes and therapies without risk to human patients. Animal models can explore the degree to which stress modulates a variety of factors that operate inside the stomach, such as acid and other secretions, and stomach contractions, and determine whether and how they contribute to the production of ulcers.

First efforts with animal models to explore the ulcerative process(es) were by physiologists following up on the strong physical challenges pioneered by Selye, such as total immobilization often combined with cold. Many factors were identified as participatory, but the actual local gut mechanisms for the induction of gastric erosions and ulcers were not fully understood because of the number of interacting processes involved. Although the causal chain was not fully described by these studies, the roles of the vagus nerve (the major nerve pathway between the brain and the gut, and vice versa) and histamine release in the stomach were established, leading to development of surgical interventions and modern medications.

Nonetheless, even with later more extensive knowledge about local mechanisms, the determinants

of who will get an ulcer and when were still not understood. These physiological models focused on biology, but Selye indicated that psychological factors, missing from these physiological studies, were likely contributors as well.

One focus of psychological studies was behavior. Activity is a factor for ulcer induction. It has long been known that systematically controlled temporal schedules of access to food induce a variety of behaviors, and such behaviors are directly correlated with stomach activity. Prolonged exposure to the combination of restricted access to food for 1 or 2 hours *once* each day results in spontaneous increases in running, the development of gastric ulcers after several days, and even death. These "activity stress" ulcers are not due per se to either restricted food or access to the running wheel, but to the combination of these factors and the dramatic increases in activity. The phenomenon is readily demonstrable in a variety of species, and interest in this ulcer model has been sustained by an analogy to anorexia nervosa, the self-starvation that afflicts many young women today.

Other early psychological models demonstrated that psychological factors related to coping with stress rather than physical/physiological factors were causal in ulcer induction. An early example of such a model Joseph Brady called the "executive monkey" experiments. Two monkeys were initially set to the task of learning to press a lever to avoid delivery of a brief, mild electric shock. The monkey that seemed to be learning the avoidance task faster was then designated the "executive" and, from that point on, only its responses controlled shock deliveries, although if the executive received a shock, they both did. Thus, the monkeys were equated for physical experiences (shocks) but they differed in their fear of shocks (the faster learner was designated the executive) and their avoidance behavior. The outcome of this arrangement was unexpected. After some weeks, the executive monkey died and autopsy revealed that it had massive ulcers in the stomach. These experiments have been criticized on a number of grounds. Yet they did make clear that animals with identical physical experiences with shock but with different psychological relations to the shock were differentially vulnerable to ulcers. That is, the ulcers were a psychosomatic disorder, a disorder in which psychological variables were powerful contributors. Although this paradigm proved not to be widely generalizable, it did stimulate others to seek to demonstrate in different animal models that

psychological factors play a role in the gastric ulcer process.

### NEWER STRESS-DIATHESIS APPROACHES

Newer approaches see ulcer as a product of several causal factors, including constitutional predisposition, and precipitated by a particular event or stressor. Several factors predisposing to gastric ulceration when an organism is stressed were noted above, but *how* these influence vulnerability is neither always obvious nor direct. For example, age at weaning is one critical factor. Rats weaned early are more vulnerable to ulcerations and this was initially attributed to social-psychological trauma. But detailed follow-up studies revealed the actual mechanisms to be early malnutrition resulting in later poorer thermoregulation when challenged with restraint and cooling.

Life is a continuing series of biological-developmental-experiential events all of which have their cumulative and interacting effects on the organism. With respect to virtually any disorder, the most sensible appreciation of complexity distinguishes three classes of causal factors: *predisposing*, *precipitating*, and *perpetuating*. Each of these types of causal factors may be physiological or psychological. We shall now consider some of the evidence for psychological contributions in each of these phases.

#### Predisposing

Rather than seeking a psychological manipulation that can be said to be directly causal of ulcer, Robert Murison and Bruce Overmier looked for psychological manipulations that modulate the organism's vulnerability to some separate ulcer-inducing event. The latter could be a stressor or even a bacterial infection. A series of researchers asked how past experiences and psychological variations in these can increase or decrease vulnerability to a stressor of known ulcerogenicity, in their case, restraint and partial immersion in water (RIW). This RIW method for reliably precipitating ulcers is to vertically suspend a fasted rat moderately restrained inside a tube in a bath of room temperature water. This "physical" ulcer-inducing challenge itself may well have psychological components to it because it is ulcerogenic only in conscious animals.

The protocol calls for exposing the animals to a first stressor and then at some later time exposing the

animals to the RIW challenge. The question asked is what features of the first stressor, if any, influence the relative vulnerability to the ulceration induced by the second challenge. The modulatory effects could be to either exacerbate or ameliorate the vulnerability to the directly induced gastric erosions.

For psychologically relevant variations, they turned first to the established knowledge of learned helplessness, a psychologically important stress-induction paradigm of relevance to humans, and then to classical conditioning and instrumental learning, core psychological strategies for coping with and adapting to environmental challenges. It is well established that prior coping experiences facilitate later learning while noncoping has later pathological consequences. Initial studies showed a dramatically increased vulnerability to ulcers following earlier exposure to uncontrollable and unpredictable stressful events such as electric shocks known to induce helplessness. Given that treatments that induce learned helplessness also increase vulnerability to gastric erosions, would treatments that prevent learned helplessness, like the ability to control the shocks, also modulate the increased ulcer vulnerability?

*Controllability.* There are several forms of control over shocks that might be relevant: control over shock onset, severity, or duration. One study compared three groups of rats that differed only in the initial shock treatment. There were control rats that received no shocks, escape rats that received shocks the onsets of which were unpredictable and uncontrollable but the durations of which were controlled by the rats pressing a lever to escape the shocks, and yoked rats that received shocks of exactly the same numbers and durations as did the escape rats but who themselves had no control. The yoked rats showed the greatest amount of erosions and 3 times more than the escape rats after later RIW. Thus, controllability of aversive events determines the long-term aftereffects of the experience as a modulator of vulnerability. In addition, the level of erosions in the control rats was intermediate between the levels seen in the escape rats and the yoked rats. This study confirmed the negative consequences of unpredictable, uncontrollable shocks, but the pattern also revealed a new effect. This is that prior coping experience *reduces* vulnerability to later challenges, a kind of "learned mastery" effect, opposite of learned helplessness.

*Predictability.* In the helplessness literature, most attention has been given to the importance of escape, but learned helplessness has multiple symptoms that may have different experiential causes. In particular, lack of predictability has been shown to interfere with subsequent associative learning just as lack of controllability interferes with subsequent instrumental learning. There are several forms of predictability of shocks: of shock onsets, of shock severity, of the end of the shocks, and prediction of the period of safety between shocks; the effects of these may differ. What might one expect as a result of signaling shocks? One possibility is that it reduces the surprise and hence reduces the aversiveness of each shock; alternatively, the warning could elicit anxiety and increase the total stress experience, with consequences for increased vulnerability to later ulcerogenesis.

One experiment included a test of whether signaling of shock onsets by a conditioned stimulus (CS) during exposure to uncontrollable shocks would modulate their exacerbatory influence. Three groups were compared: rats that experienced no shocks prior to the RIW challenge, rats that experienced unpredictable shocks (that were also uncontrollable), and rats that had the same shocks but each was preceded by a warning signal. Although prior exposures to shocks proactively increased vulnerability to the ulcerogenic challenge as expected, signaled shocks did so to a substantially lesser degree. Signaling the uncontrollable shocks reduced vulnerability relative to the effect of unsigned shocks.

A second form of predictability is provided by a stimulus that immediately follows each shock. This paradigm is called backward conditioning and it allows prediction of the safe period that typically follows each shock. It also coincides with the "relief" that follows pain, and is known to classically condition an "opponent process" that is the opposite of that conditioned by signals for shock onsets. The influence of this second form of signaling has also been assessed. Three groups of rats differed in their treatments before the water challenge: one group received no shocks, another received a series of shocks and an equal number of tones that occurred randomly in time, and the third group received the same series of shocks each one followed immediately by the tone backward CS. The rats that had had the backward CS showed only one fourth as much gastric erosion in response to later RIW challenge as did the rats that had not had this backward CS. That is, signals at the end of shocks

appear to be functionally equivalent to a controlling response that terminates shocks in terms of reducing the increase in ulcer vulnerability.

### Precipitating

An early study by Martin Seligman linked the learned helplessness paradigm to ulcer, a symptom that is elevated in depressed patients. Unlike the proactive studies described above, here the ulcer-precipitating stress was shock itself. Rats exposed on each of several days to the learned helplessness treatment of uncontrollable and unpredictable shocks showed greater gastric ulceration than those that received predictable, uncontrollable shocks. This particular experiment, however, was seriously confounded by differences in food consumption between the two groups, with the rats in the helplessness condition eating substantially less, and it is known that self-starvation can result in gastric erosions. Nonetheless, the helplessness experiments stimulated new interest in controllability and predictability of aversive events as important modulating factors.

An excellent set of studies by Jay Weiss on the importance of controllability and predictability as modulators of stress in the production of ulcers studied independently and interactively the psychological factors of prediction and control concurrently. Triplets of animals were studied with (1) one "master" trained on a temporally paced escape/avoidance task, (2) one having ineffective responses but receiving in "yoked" fashion all the events that the master received, and (3) one with ineffective responses that also never received shocks. There were two types of triplets: for one, all shocks were predictable, whereas for the other, no shocks were predictable. After 48 hours under these conditions, gastric ulceration was reduced by prediction and by control and these were additive. The importance of control is independent of the particular coping response, although the reliability and precision of control are important as is feedback that the correct response has been performed.

Taken together, these studies show that when behavioral treatments that support instrumental or classical forms of learning are a concurrent part of a stress situation, these psychological variations are important modulators of the degree of stress-induced ulceration. Intriguingly, behavioral opportunities to act-out aggressively concurrent with the shock stress have also been shown to ameliorate the degree of

ulceration. The opportunity to attack a conspecific or engage in other natural defensive coping behaviors when under threat and/or experiencing pain reduces the gastric ulcer consequences of aversive experiences.

An alternative approach emphasized that *conflict* was a powerful source of psychological stress that might be directly ulcerogenic. A series of experiments was carried out in which rats were placed in an approach-avoidance conflict situation. A typical arrangement was for the animal to first learn to earn its food and water, and then an additional contingency was imposed such that seeking food *also* resulted in the delivery of a brief, mild electric shock. Thus, the animal was believed to suffer the clash of incompatible motivational states and, indeed, rats exposed to such conflict for 30 days showed more ulcers than those merely deprived of food. Later experiments with better controls confirmed the result and established that the shocks per se were not ulcerogenic. However, other experiments directly challenge conflict as the cause of ulcers. William Paré compared water-deprived rats subject to daily conflict in which they had to accept shocks to obtain water with yoked rats that received matched amounts and distributions of shocks and water. Importantly, because these rats were not chronically food deprived, we can infer that any ulcers observed were predominantly glandular. The result was that the control rats developed more ulcers than did the rats experiencing conflict.

In overview, those studies testing the ulcerogenicity of conflict have not convincingly demonstrated it to be a causal factor in ulcerogenesis. Rather, they seem to have identified exposure to the stress of aversive stimulation that suppressed food intake as the central causal factor.

Several different methods have been tried to induce gastric ulcerations in a search for a purely *psychological* cause. These studies have each presented to the organism some challenge that had physical threat components accompanied by an associated behavioral/psychological component. The combination of these resulted in amounts of ulceration not fully accounted for in terms of the physical treatment alone. Thus, these studies have shown some psychological and cognitive factors to be important, particularly control and predictability of aversive events, and these act to ameliorate ulcerations. None of the reviewed studies have found evidence for a purely psychological cause of ulcerations.

## Perpetuating

Do manipulations after an ulcerogenic stress have significant effects on perpetuation of ulcer? The question is whether during a *post*-gastric ulceration “rest” period includes signals for danger. Murison and Overmier demonstrated that psychological treatments after ulcer induction could influence the sustaining process; their work involved a comparison of three groups. One group experienced only a series of neutral CSs prior to the later RIW challenge; the other two groups received the same CSs each paired with shock days prior to the ulcer-inducing water challenge. Then, *after* RIW, all groups were “rested” for 2 hours, during which the unshocked group and one of the shocked groups received intermittent presentations of the CSs (but without shocks). It was expected that re-presentation of CSs that had earlier been paired with shock would represent a threat to the rat and might perpetuate the ulcerative process. Exactly that was observed. The preshocked group that during rest had re-presentations of the warning CS showed dramatically more gastric ulcers. Thus, the perpetuating process can be modulated by psychological manipulations.

Consistent with a stress-diathesis model, the above experiments have confirmed that the ulceration processes can be modulated by psychological treatments in all three of the ulcerative stages, predisposing, precipitating, and perpetuating. It would be of interest to know the local gut mechanisms through which these psychological processes effect their modulation, but lack of such knowledge does not invalidate the facts.

## BACTERIA AS A DIATHESIS FACTOR

The series of studies reviewed confirms that psychological factors modulate gastric erosions in animal models, and because we know that emotional states influence the human stomach, it is reasonable to believe that such psychological factors relating to stress operate in humans as well. This implies that gastric ulcer is a “psychosomatic” disease in the sense that psychological states modulate vulnerability. However, the view of ulcerogenesis changed with Marshall’s discovery of *Helicobacter pylori* (Hp), a bacterium that infects substantial numbers. Physicians have noted that the conditional probability of infection in ulcer-presenting patients is 70% to 95% (depending on whether it is gastric or duodenal) and

that treatment of this infection eliminates the ulcer in about 80% of patients. So it is not surprising for it to be believed that Hp causes ulcers and that the clinical medical problem is solved.

The reason for a challenge to the medical hypothesis of Hp as the unique cause is that up to 60% to 80% of asymptomatic controls (depending on age) show Hp infection. Thus, while a high percentage of patients presenting with ulcer do have a bacterial infection, the inverse conditional probability of having an ulcer given that one has an Hp infection is less than 20%. In addition, another 20% of stomach ulcer patients are uninfected. Thus, Hp infection alone is an insufficient account of gastric ulcer. Unanswered are why some infected persons do not show ulcers and what it is that results in ulcers in infected persons. The answer is the classic "stress  $\times$  diathesis" interaction model in which at least one part of the diathesis is Hp infection.

Hp infection rate and cumulative life stresses are both correlated with age. In addition, Hp infection is associated with low socioeconomic status, and persons in low socioeconomic status have less control over their lives, especially in the workplace. They are also subject to greater economic stress and face more social barriers. Such persons, especially as they get older and apparent opportunities fade, are more likely to report depression, helplessness, and hopelessness. Life becomes uncontrollable and unpredictable, the very psychological factors that are important in modulation of ulcer vulnerability in animal research. This convergence of data from animal models and the epidemiological literatures suggests that at last we are beginning to understand the causes of gastric ulceration.

#### FUTURE RESEARCHES ON GASTRIC ULCER

Something is modulating vulnerability to Hp associated ulcer. Among these, Susan Levenstein has identified past life challenges as important risk factors, as well as a number of other social and behavioral factors. Thus, any future research strategy for animal models that seeks to link past research programs to human disease must study the interaction of (a) psychological modulators of the types that research has validated as relevant, (b) immunologic status and bacterial exposure, and (c) current physical or psychological stress. There also exist parallels between the psychologically relevant operations that modulate

gastric vulnerability and those that modulate immune status. This last relation is made more significant by recent findings that local target actions of some new potential antiulcer drugs may be the immune system. Such psycho-immuno-ulceration experiments may be seen as a potential final hurdle in our understanding of gastric ulcers.

Whatever the outcome of these researches, it is clear that the causes of ulcer are complex and hence that the optimal treatments involve more than antibiotics, and must involve additional efforts to address the individual's sources of stress and coping inefficiencies as well as lifestyle and socioeconomic interventions. Gastric ulcer is the epitome of a socio-psychological-biomedical dysfunction.

## GATE CONTROL THEORY OF PAIN

---

The specificity theory of pain that we inherited in the 20th century derives from a concept of the nervous system proposed by René Descartes three centuries earlier. Specificity theory maintains that injury activates specific pain receptors and fibers, which, in turn, project pain signals through a spinal pain pathway to a pain center in the brain. The psychological experience of pain, therefore, is virtually equated with peripheral injury. In the 1950s, there was no room for psychological contributions to pain, such as attention, past experience, and the meaning of the situation. Instead, pain experience was held to be proportional to peripheral injury or pathology. Patients who suffered chronic pain syndromes without presenting signs of organic disease were labeled “crocks” and sent to psychiatrists. The picture, in short, was simple. However, to thoughtful clinical observers, it was clearly wrong (Livingston, 1943; Noordenbos, 1959).

In 1965, Melzack and Wall proposed the gate control theory of pain, based on the following propositions:

1. The transmission of nerve impulses from afferent fibers to spinal cord transmission cells is modulated by a spinal gating mechanism in the dorsal horn.
2. The spinal gating mechanism is influenced by the relative amount of activity in large-diameter and small-diameter fibers: Activity in large fibers tends to inhibit transmission (close the gate), while small-fiber activity tends to facilitate (open the gate).
3. A specialized system of large-diameter, rapidly conducting fibers (the *central control trigger*) activates selective cognitive processes that then influence, by way of descending fibers, the modulating properties of the spinal gating mechanism.
4. When the output of the spinal cord transmission cells exceeds a critical level, it activates the *action system*—those neural areas that underlie the complex, sequential patterns of behavior and experience characteristic of pain.

When the gate control theory was published, it generated vigorous debate as well as a great deal of research to disprove or support the theory. By the mid-1970s, the theory was presented in almost every major textbook in the biological and medical sciences. At the same time, there was an explosion in research on the physiology and pharmacology of the dorsal horns and the descending control systems.

The theory's emphasis on the modulation of inputs in the spinal dorsal horns and the dynamic role of the brain in pain processes had a clinical as well as a scientific impact. Psychological factors, which were previously dismissed as “reactions to pain,” were now seen to be an integral part of pain processing, and new avenues for pain control were opened. Similarly, neurosurgical procedures such as cutting nerves and spinal pathways have been gradually replaced by a host of methods to modulate the input. Physical therapists and other health care professionals who use a multitude of modulation techniques were brought into the picture. The current status of pain research and therapy has recently been evaluated (Melzack & Wall, 1996) and indicates that, despite the addition of a massive amount of detail, the theory remains basically intact.

The gate control theory's most important contribution to pain research and therapy is its emphasis on the central rather than the peripheral nervous system (Melzack, 1998, 1999; Melzack & Wall, 1996). Knowledge of spinal mechanisms has advanced enormously (Wall & Melzack 1999), and the great challenge at present is to understand brain mechanisms. Melzack and Casey (1968) made a start by proposing that specialized systems are involved in the sensory-discriminative, motivational-affective, and cognitive-evaluative dimensions of pain. So too, the McGill Pain Questionnaire, which taps into subjective experience generated by the brain, was developed and is widely used to measure pain (Melzack, 1975, 1987).

The gate control theory also postulated that the brain exerts a tonic inhibitory effect on pain, which led directly to the discovery by Reynolds (1969) that electrical stimulation of the midbrain periaqueductal gray (PAG) area produces analgesia. Subsequent research (Liebeskind & Paul, 1977) revealed that the PAG contains pharmacological substances such as endorphins that contribute to the descending inhibition. Later, a series of definitive studies on “diffuse noxious inhibitory controls” (DNIC) firmly established the power of the brain in controlling spinal

transmission (Fields & Basbaum, 1999; Le Bars, Dickenson, & Besson, 1983).

In 1978, Melzack and Loeser described severe pains in the phantom body of paraplegics with verified total sections of the spinal cord, and proposed a central “pattern generating mechanism” above the level of the section. This concept represents a major advance: It does not merely extend the gate; it proposes that pain can be generated by brain mechanisms in paraplegics in the absence of sensory input from the body area that is perceived as painful.

It is evident that the gate control theory has taken us a long way. Yet, as historians of science have pointed out, good theories are instrumental in producing facts that eventually require a new theory to incorporate them. It is possible to make adjustments to the gate theory so that it includes postinjury expansion of peripheral receptive fields and long-lasting neural activity (see Melzack & Wall, 1996). But there is a set of observations on pain in paraplegics that does not fit the theory. This does not negate the gate theory, but rather incorporates it into a broader conceptual system. Peripheral and spinal processes are obviously an important part of pain and we need to know more about the mechanisms of peripheral inflammation and spinal modulation. But the data on painful phantoms below the level of total spinal section (Melzack, 1989, 1990) indicate that we need to go above the spinal cord and into the brain.

The brain areas related to pain involve more than the spinal projection areas in the thalamus and cortex. These areas are important, of course, but they are only part of the neural processes that underlie perception, emotion, and cognition, which are all part of pain experience and behavior. The cortex, Gybels and Tasker (1999) have made amply clear, is not the pain center and neither is the thalamus. The areas of the brain involved in pain experience and behavior must include these somatosensory projections and, in addition, must also include the limbic system as well as widespread areas of the brain known to be involved in cognitive processes.

An analysis of phantom limb phenomena, particularly the astonishing reports of a phantom body and severe phantom limb pain in people after a cordec-tomy—that is, complete surgical removal of several spinal cord segments—led to four conclusions that point to a new conceptual nervous system (Melzack, 1989, 1990). First, because the phantom limb (or other body part) feels so real, it is reasonable to

conclude that the body we normally feel is subserved by the same neural processes in the brain; these brain processes are normally activated and modulated by inputs from the body but they can act in the absence of any inputs. Second, all the qualities we normally feel from the body, including pain, are also felt in the absence of inputs from the body; from this we may conclude that the origins of the patterns that underlie the qualities of experience lie in neural networks (or *neuromatrixes*) in the brain. Stimuli may trigger the patterns but do not produce them. Third, the body is perceived as a unity and is identified as the “self,” distinct from other people and the surrounding world. The experience of a unity of such diverse feelings, including the self as the point of orientation in the surrounding environment, is produced by central neural processes and cannot derive from the peripheral nervous system or spinal cord. Fourth, the brain processes that underlie the body-self are “built-in” by genetic specification, although this built-in substrate must, of course, be modified by experience. These conclusions are the basis of the neuromatrix theory of pain—the most recent conceptual model that has evolved from the gate control theory (Melzack 1989, 1990, 2001).

The neuromatrix theory of pain proposes that the anatomical substrate of the body-self is a large, widespread network of neuron loops between the thalamus and cortex as well as between the cortex and limbic system. Melzack has labeled the entire network, whose spatial distribution and synaptic links are initially determined genetically and are later sculpted by sensory inputs, as a neuromatrix. The loops diverge to permit parallel processing in different components of the neuromatrix and converge repeatedly to permit interactions between the output products of processing. The repeated *cyclical processing and synthesis* of nerve impulses through the neuromatrix imparts a characteristic pattern: the *neurosignature*. The neurosignature of the neuromatrix is imparted on all nerve impulse patterns that flow through it; the neurosignature is produced by the patterns of synaptic connections in the entire neuromatrix. All inputs from the body undergo cyclical processing and synthesis so that characteristic patterns are impressed on them in the neuromatrix. Portions of the neuromatrix are specialized to process information related to major sensory events (such as injury, temperature change, and stimulation of erogenous tissue) and may be labeled as neuromodules that impress subsignatures

on the larger neurosignature. The neurosignature, by means of mechanisms that remain a challenge to research, converts the stream of nerve impulses (the neurosignature modulated by ongoing inputs) into a continually changing stream of awareness.

The body is felt as a unity, with different qualities at different times. Melzack proposes that the brain mechanism that underlies the experience comprises a unified system that acts as a whole and produces a neurosignature pattern of a whole body. The conceptualization of this unified brain mechanism lies at the heart of the neuromatrix theory. Melzack visualizes a genetically built-in neuromatrix for the whole body, producing a characteristic neurosignature for the body that carries with it patterns for the myriad qualities we feel. The neuromatrix produces a continuous message that represents the whole body in which details are differentiated within the whole as inputs come into it. We start from the top, with the experience of a unity of the body, and look for differentiation of detail within the whole. The neuromatrix, then, is a template of the whole, which provides the characteristic neural pattern for the whole body (the body's neurosignature) as well as subsets of signature patterns (from neuromodules) that relate to events at (or in) different parts of the body.

The experience of the body-self involves multiple dimensions. The sensory dimension is subserved, in part at least, by portions of the neuromatrix that lie in the sensory projection areas of the brain; the affective dimension is subserved by areas in the brainstem and limbic system; the cognitive dimension is determined by the frontal, parietal, and other cortical areas. Each major psychological dimension (or quality) of experience is subserved by a particular portion of the neuromatrix that contributes a distinct part of the total neurosignature. To use a musical analogy, it is like the strings, woodwinds, and brasses of a symphony orchestra that each comprise a part of the whole; each makes its unique contribution yet is an integral part of a single symphony, which varies continually from beginning to end.

The output of the body-self neuromatrix, Melzack (1991, 2001) proposes, is directed at two systems: (1) the neural system that produces awareness of the output and (2) a neuromatrix that generates overt action patterns. In this discussion, it is important to keep in mind that just as there is a steady stream of awareness, there is also a steady output of behaviour.

It is important to recognize that behavior occurs only after the input has been at least partially synthesized and recognized. For example, when we respond

to the experience of pain or itch, it is evident that the experience has been synthesized by the body-self neuromatrix (or relevant neuromodules) sufficiently for the neuromatrix to have imparted the neurosignature patterns that underlie the quality of experience, affect, and meaning. Apart from a few reflexes (such as withdrawal of a limb, eye-blink, etc.), behavior occurs only after inputs have been analyzed and synthesized sufficiently to produce meaningful experience. When we reach for an apple, the visual input has clearly been synthesized by a neuromatrix so that it has 3-dimensional shape, color, and meaning as an edible, desirable object, all of which are produced by the brain and are not in the object "out there." When we respond to pain (by withdrawal or even by telephoning for an ambulance), we respond to an experience that has sensory qualities, affect, and meaning as a dangerous (or potentially dangerous) event to the body.

—Ronald Melzack

## GENDER DIFFERENCES IN HEALTH

---

Differences between men and women in relation to their social lives, activities, roles, behaviors, and longevity have existed for centuries. Until recently, these differences have almost been taken for granted and largely ignored. Increased research concerning health inequalities and inequities based on socioeconomic position seems to have contributed to the growing interest in gender inequities in health. It has thus become inevitable to address health inequalities and inequities based on gender, as it is a major component of social construct besides socioeconomic position

and race or ethnicity. Even the World Bank has acknowledged that economic development in the low-developed economies cannot be enhanced without addressing issues of gender equity.

This entry highlights gender inequity in health, by defining and analyzing differentials in men and women not only in relation to morbidity, mortality, and health care access and utilization but also the determinants of gender disparities in health that operate at both macro and micro levels.

## GENDER DIFFERENCES IN MORBIDITY

According to the World Health Organization (WHO), morbidity is measured as the incidence or prevalence of the presence of illness or injury. Health surveys and statistics consistently demonstrate that women have higher morbidities of a wide range of health indicators than men, including physical illness, disability days, physician visits, and drug use. Men have higher rates of more serious chronic diseases and long-term disability due to chronic conditions leading to death. Injury rates are higher among younger men, but among the elderly, women have higher rates, particularly for mortality.

There are a number of explanations for high morbidity in women and high mortality in men. In a review of literature, Verbrugge (1989) identified short- and long-term morbidities and noted that in the short run women are more frequently sick, with higher rates of daily symptoms and higher incidence rates of acute illness. In the long-run women have higher rates of numerous nonfatal chronic conditions that lead to abundant symptoms, disabilities, and medical care, but not to death. Men's higher mortality is thus linked to higher rates of life-threatening chronic conditions, such as ischemic heart disease.

Generally, there are varying biological susceptibilities to disease that expose men and women to different morbidities. For example, women's unique reproductive health exposes them to specific morbidity risks that are not present in men. On the other hand, women have genetic resistance to diseases such as those related to X-chromosomes. Women's sex hormones protect them from cardiovascular morbidity until menopause, whereas men lack such protection and are thus more susceptible to cardiovascular morbidity 10 years earlier than women. The seemingly more advantageous biological protection for women's mortality, however, does not fully explain why women

have higher morbidity rates, ranging from short-term to long-term disabilities, including acute conditions, chronic diseases, headaches, and musculoskeletal diseases. Thus, other factors besides biology, such as social, behavioral, and cultural factors, are important determinants of well-being and should not be ignored.

Sharp gender differences are observed in psychiatric and psychological disorders, where women have increased burden of such disorders. Depression warrants special attention in this respect. Statistically, women are overrepresented in the prevalence of depression in many countries. Depression is a serious health disorder that predicts life-threatening health outcomes such as coronary heart disease (CHD). Depression has also been identified by the WHO global burden disease study as the fourth largest global health problem, which is predicted to rank second in 20 years time, that is, following cardiovascular disease.

As Macintyre and Hunt (1997) stated, gender differences in health are not as simple. They are conceptual and methodological problems, particularly concerning interactions of gender with other social factors that should be considered. Self-rated health, for example, which is universally used to estimate health or illness, may not be the most suitable indicator for addressing gender differences in health. Health or illness may mean different things for men and women, as they may differentially perceive and evaluate symptoms, along with other influences, such as social context, cultures, or traditions. Methodologically, statistics from the health surveys on morbidity are often based on health problems that prevent people from doing their regular major activities and need for medical care. Health problems that are acted on by nonmedical health professionals and other self-care activities are not well captured in health statistics, and thus do not provide the clear picture of health problems that influence men's and women's daily lives.

## GENDER DIFFERENCES IN MORTALITY

Life expectancies in men and women differ from country to country and are dependent on overall national economic development, specific aspects of gender inequities within those countries, and the relevant health problems. For example, in sub-Saharan Africa where HIV/AIDS is the major cause of death, a higher mortality is obvious in women than in men.

In Western societies where cardiovascular disease is the major cause of death, a higher mortality is observed in men than in women.

Another major explanation is that related to alcohol consumption. For example, the increasing male-female gaps in mortality rates in Russia may largely be attributed to high alcohol consumption among men. In Sweden, the male-female gaps in mortality narrowed from the 1980s, which paralleled decreased alcohol consumption, particularly among men.

Lawlor, Ebrahim, and Davey-Smith (2001) observed that while some of the differences in men's and women's life expectancy certainly reflect biological influences, it is clear that biology alone is an incomplete explanation. Social conditions affect women's health beyond biological differences. The biological protection against early death, whereby women have higher life expectancy than men, is not uniform in all countries and not defined in various socioeconomic positions. According to the *WHO Health Report* (World Health Organization, 1999), poor women have lower life expectancy than poor men. In societies where women's social status is very low, in addition to lack of resources for education of girls and lack of investment in women's health care, women are more likely to have poor nutrition, less access to health care, lower economic autonomy, shorter spacing and a larger number of births, poor maternal health care, and higher maternal and infant mortality. Therefore, gender differences in health may be better understood by analyzing the social, cultural, and structural dimensions of gender relations including investigating the nature of social systems, men's and women's structural place, and the roles they play within those systems.

## GENDER DIFFERENCES IN HEALTH CARE ACCESS AND UTILIZATION

Generally, women have been reported to visit health care professionals more frequently and to consume more pharmaceutical drugs than men. Women value health and more often seek care in the initial stages of a health disorder, and they are more willing to take actions for their symptoms than men. In spite of this phenomenon, studies in the United States, the United Kingdom, and Sweden indicate that complicated or specialist-based diagnostic and therapeutic procedures are less often applied to women than to men. An evaluation of behaviors among health care

professionals in 45 different primary care centers in the United Kingdom in 2001 demonstrated that screening and treatment of cardiovascular risk factors were less often done for women than for men, including less complicated registrations of smoking status, family history, height, weight, and blood pressure.

Even in Sweden where health care is publicly financed by the tax revenues, gender inequities in rehabilitation programs have been observed over a long period of time. Today, over 60% of the individuals who are on long-term sick leave are women. In spite of this, official statistics show that men's rehabilitation cost is about 4 times more than that given to women and that women are more likely to receive a much shorter and less aggressive rehabilitation than men.

On the contrary, women in less developed societies less frequently visit health care professionals, further contributing to late and inappropriate medical care. There are various explanations for this, such as poor infrastructure, lack of economic resources, longer distance between home and health center, refusal of the husband's permission, or knowledge deficiency due to low education.

An attempt toward broader understanding of gender differences in health can be found in Wamala and Lynch's (2002) volume that integrates gender with socioeconomic position, culture, and ethnicity. They demonstrated that an evaluation of how men and women access or possess health-promoting and protective resources, encounter health-damaging exposures, and develop susceptibilities to physiological exposures is of great importance. Such an approach may provide a broader understanding of gender differences in health, other than just focusing on the statistical differences in rates of morbidity and mortality and how health care is utilized. As Sen (1995) suggested, gender differences in health should be regarded in terms of both inequalities (the measurable) and inequities (the moral judgment).

## MACRO-LEVEL ASPECTS OF GENDER DIFFERENCES IN HEALTH

### Gender Construction and Stratification

In spite of the fact that gender and sex mean different things, the two terms have often been used interchangeably to mean the same thing. Even in various scientific reports, *gender* has been used to replace *sex* particularly in statistical tables.

Sex refers to the biological differences: genetic, anatomical, and physiological differences that indicate whether one is a female or male and their implications on health susceptibilities or immunities. Gender, on the other hand is a social construct, associated with how males and females are organized in the society and the associations with power relations, behaviors, and roles that place them at an advantage or disadvantage over access and control of (health promoting) resources.

The association between gender and health can also be better understood by addressing the key characteristics of gender, which include gender roles, access to and control of resources, contextual aspects, and structural issues. It should be noted, however, that gender as a concept is not static—it is as dynamic as society. The roles and relations between men and women in a given society, therefore, vary from one generation to another, and change as the social norms and values change in a given society. Also, gender characteristics may be modified by interventions toward gender equity.

### Gender Roles

Gender roles refer to the different social roles that men and women play. The relationships between men and women are socially constructed and defined by these roles. Although these roles can be gender specific, they are culturally defined and learned throughout the life course. There are no universal roles specific to men or women; these roles vary with different cultures, because of different levels of economic growth and differing traditions, expectations, psychological processes, and behaviors. However, in almost all cultures women have greater responsibility for not only domestic activities (such as child care, household tasks) but also wage-earning activities and heading the family. The recent developments in gender roles where men in many societies have surrendered their traditional role of wage earner and being the head of the family are disturbing. Many women today are faced with a wide range of roles including wage earning, domestic tasks, parenting and raising children single handed, and care of old and sick relatives.

There has been a transition from the traditional sex-role ideologies that men are more important than women and that they should dominate and control women to modern ideologies that emphasize equality

between men and women. The modern ideologies have been more successful in Western societies where there are high levels of democracy, with the exception of a few, such as Japan.

Women's participation in the labor force has been a major contribution to the modern ideologies of gender equality. In some societies, however, women's participation in the labor force by itself has not changed the traditional sex-role attitudes. A cross-cultural comparative study by Atsuko Suzuki showed that working North American women regardless of occupational status had more equality than nonworking women. In Japan, however, attitudes toward gender equality demanded more than just being employed—those with professional jobs were more egalitarian than others. Studies in egalitarian Sweden show that partners of women who hold career-oriented professional jobs are more likely to share domestic work than partners of women who hold less career-oriented or low-status jobs. Women's occupational status provides them with bargaining power not only at home but also in the society, and it is thus an important contributing factor to gender equality.

Feldman (2001) further suggested that gender roles and their impact on health can be better understood by evaluating not only the "quantity" but also the "quality" of these roles.

Macroeconomic forces, including distribution of power that influences division of domestic tasks and labor segregation that forces women into lower-status jobs, substantially influence the type of roles that men and women play in society.

### **Gender Differences in Access to and Control of Resources**

The differences between men and women are not neutral, which creates a hierarchical phenomenon. The pattern of access to and control of resources is an important determinant of how different hierarchical positions of men and women in society are created and maintained. The *Human Development Reports* of the United Nations Development Programme (UNDP) indicate huge global gender inequalities in social indicators (such as education, poverty, credit, and employment opportunities) that influence population health. For example, data from the UNDP indicate that 25% of families globally are headed by women. Yet 60% of the world's illiterate are women and earn only 10% of

the world's income, which is not surprising given that 70% of the world's poor are women.

There are several examples of how women's position in society is valued. For example, in Sweden where gender equality is among the best developed in the world, women earn 10% to 20% less than men at the same occupational level and with the same level of educational attainment. This pattern has remained unchanged for the past 20 years. Women's incomes are less than men in all socioeconomic groups. Women's short-term and low-paid employment are reflected by their socioeconomic disadvantage and economic instability, which further decreases their power to influence decisions, such as resource allocation and investment decisions, even within their own households. This is especially important for public health, as so many children are solely dependent on women. There are different economic implications of separation or divorce for men and women. Generally, women's income decreases after separation, while men's income increases. The negative consequences of socioeconomic disadvantage are detrimental not only to women's health but also to their children and may influence the entire lifecycle and create a vicious cycle of poverty.

Power can be analyzed in relation to knowledge, economic resources, decisions, and exploitation and operates at both interindividual and institutional levels. Even in democratic societies today, women still suffer negative effects of patriarchal and male-dominated society. Men's values still determine the norms of both public health policies and general medical practice. The persistently small number of women in national scientific academies even in highly democratic societies such as those in Western Europe and North America could be a reflection of unequal distribution of power in relation to knowledge.

The domestic power imbalance contributes to how gender roles are valued and ultimately affects gender inequity in society. Household income, for example, is not usually equally distributed, mainly because men often have higher incomes than women and thus greater control of the household income. Power imbalance may be misused, and may result in domestic violence.

Violence varies between men and women. While men's violence is often self-inflicted, violence-related injuries in women are often inflicted on them by others, often a male relative, mostly a partner.

### Contextual Aspects of Gender

Gender roles and relationships vary with cultural concept, birth cohort, and the ethnic and socioeconomic groups to which men and women belong. Thus, characteristics that are specific to a particular group of men or women should not be generalized to all men or women in different ethnicities, socioeconomic positions, or age groups.

Globalization processes that have resulted in increased migrations into Western countries demand broader knowledge of not only the gendered economy but also gendered culture within multicultural societies. Multiculturalism has led to the construction of “the other” woman. Women with other ethnic backgrounds that differ from those of “White” women have often been regarded as invisible and actually seen as a problem for feminists, particularly in Scandinavian countries. Gender order, particularly in White-dominated societies such as those of Scandinavia, has been mainly based on the norms of White men and women, ignoring the aspects of other ethnicities. Thus, gender should incorporate other domains of social construct, that is, socioeconomic position and ethnicity/race.

### Structural Issues Concerning Gender

Gender refers not only to interpersonal relations between men and women but also to the structural relations at a societal level that create and support the type of career choices and professions that men and women take on, gender values and beliefs that influence the type of health care and services that men and women receive, and their involvement in politics, business, and science.

The most obvious institutionally structured relation between men and women is observed in the labor market. Labor segregation in the labor market is apparent in many countries over the world. Labor segregation consists of both vertical<sup>1</sup> segregation and horizontal<sup>2</sup> segregation.

Female-dominated jobs are usually of lower status, characterized by higher demand, lower control and autonomy, and lower income, whereas male-dominated jobs are often of higher status, characterized by higher autonomy, higher control, and higher income and more favorable benefits. Due to labor segregation, men and women are exposed to varying health-damaging or health-promoting factors. For example, men

are more likely to be exposed to physical hazards (such as noise, vibrations, heavy lifting), whereas women are more likely to be exposed to psychosocial-related hazards (such as lack of control, high mental demand, lack of influence, lack of career possibilities).

### Policy Approaches to Gender Equity in Health

Gender equity refers to fair and just distribution of benefits and responsibilities between men and women, by recognizing the fact that men and women have different needs, access, and power.

Steps to successful policy approaches include analyzing gender roles, evaluating access to and control of resources that are vital for health-promoting purposes, and analyzing men’s and women’s needs in relation to their health. There are potential structural, legal, political, economic, and ideological processes that lead to gender differences in health that can be intervened upon.

## MICRO-LEVEL ASPECTS OF GENDER DIFFERENCES IN HEALTH

### Gender Differences in Behaviors

There is a range of differences in behaviors in men and women that may explain gender differences in health. For example, choices for leisure activities differ in men and women; men choose more aggressive and injury-related hobbies and sports than women do. Women’s and men’s social roles influence their behaviors toward children and other relatives; it is plausible that women’s high risk of flu and colds could be attributed to their more frequent contact with children and older people than men have. Men have more reckless health habits such as smoking and driving when drunk, which contribute to their higher prevalence of lung cancer and traffic accidents, respectively. Women’s multiple roles make them more vulnerable to psychological distress of anxiety and depression and guilt feelings and may contribute to their physiological reactions that differ from those of men.

Gender stereotyping of behaviors has been based mainly on biological differences in androgens (sex hormones that are produced in males in greater amounts than in females). Masculine and feminine behaviors have been attributed to the magnitude of exposure of androgens during critical periods of the

fetal stage. Udry, Morris, and Kovenock (1995) demonstrated that androgens are biologically programmed from fetal stage—meaning that individuals whose testosterone levels were high during the fetal stage remain high even in adulthood. Behavior is thus said to be biologically programmed and that it may not alter.

The theories about androgens and stereotyped feminine or masculine behaviors appear to be unrealistic and have often been criticized. This is because there are few men and women who possess all the characteristics that are stereotypically masculine or feminine, respectively. Gender stereotyping is complicated and misleading as the stereotyping does not seem to apply to older persons, minorities, or disabled persons.

In addition, scholars of stress demonstrate that the direction of association between behavior and androgens is not so simple. Lundberg and Frankenhaeuser (1999), in a study of physiological reactions to stress, showed high levels of stress to influence androgen levels negatively. Kemper (1990) went further and speculated that increased divorce rates in the United States can be attributed to women's aggressive and assertive behavior that results from increased female testosterone levels as a reaction to women's multiple roles of participation in the labor force and the traditional role of child and family care. Lindsey (1997) noted that there is an interaction between hormones and environmental factors that ultimately affects behaviors of males and females. The social structure and environment that individuals live in may therefore have a substantial impact on their behavior and ultimate physiological reactions.

### **Gender Differences in Social Networks and Support**

Humans become humans because of other humans; this African proverb seems to fit well in many other societies and for both men and women. Facing daily life stresses or happiness alone and not being able to share these with others have been linked with poorer outcomes. Generally, women are known to be the source of social support and to be better candidates than men in creating and maintaining social networks and contacts.

As Unden and Orth-Gomér (1989) recognized, the presence of a network does not mean that it is supportive or appreciated. Thus, it is important to distinguish

various dimensions of social networks and how they influence health in men and women. Henderson, Duncan-Jones, Byrne, and Scott (1980) identified two distinguished dimensions of social support: attachment (emotional support<sup>3</sup>) and social integration (relationships to friends, neighbors, work associates, and acquaintances). Cohen, Mermelstein, Kamarck, and Hoberman (1985) further broke social integration into various functions: belongingness,<sup>4</sup> tangible support,<sup>5</sup> and appraisal support.<sup>6</sup>

Women as compared to men usually have broader social networks and seem to benefit more from social integration than from emotional support. Women usually give more than they get back from emotional relationships. While men often report their spouses to be the source of emotional support, women usually experience a more adequate and available emotional support from their friends, usually a woman friend but not a spouse. In the Massachusetts Male Aging Study and Massachusetts Women's Health Study, it was demonstrated that 66% of men and 26% of women indicated their spouse as the source of emotional social support.

The dual and balanced analyses of social relationships that include the costs as well as benefits are an important starting point in understanding gender differences and how social networks may influence health. Women's social relationships are characterized as intrusive, demanding, conflict related and unsupportive, and such relationships are indicated to be related with decreased well-being. Burg and Seeman (1994) indicated that women are particularly more vulnerable to the negative impact of their social relationships, as they get more emotionally and intensively involved in relationships than men do. Studies of negative life events demonstrate that female vulnerability is largely confined to network events.

The California study in Alameda County by Berkman and Syme (1979) was one of the first large-scale studies to investigate social networks and their effects on mortality. Overall, there was an increased mortality risk in men and women who had less social networks. Older women, however, did not benefit from extended social networks.

The findings from the California study have been replicated by several other later studies, although with mixed results for men and women. As Shumaker and Hill (1991) emphasized, analyzing the quality of social networks is important in understanding how health may be improved. This is because not all networks are good for health. Some networks encourage

smoking, drug use, and the like, and thus are detrimental not only to individual health but also to the population at large.

Cohen (1988) suggested that social networks influence health in various ways: through social (stress buffering), psychological (e.g., depression, anxiety), and behavioral (e.g., promoting healthy behaviors, compliance with medical treatments) mechanisms. Ultimately, social isolation may affect physiological systems either directly or through these mechanisms. Horsten and others (Horsten, Mittleman, Wamala, Schenck-Gustafsson, & Orth-Gomér, 2000) found associations between social isolation and metabolic syndrome<sup>7</sup> and reduced heart variability in women that were not explained by behavioral risk factors such as smoking and physical inactivity.

### Gender Differences in Physiological Responses

Physiological responses to environmental stimuli seem to differ in men and women. Behaviors, social relationships, and the roles that men and women play vary and may differentially influence how men and women physiologically respond in different situations. The roles women and men are expected to play in society influence their appraisal of family or work life. Thus, the stresses from these two domains may be perceived differently and result in varying physiological responses that ultimately influence health status.

Burg and Seeman (1994) demonstrated that women reported higher levels of marital conflicts and perceived stress from the family than did men. Men's mental stress, on the other hand, is more often experienced at work and only rarely at home. Orth-Gomér and others (Orth-Gomér, Wamala, Horsten, Schenck-Gustafsson, & Mittleman, 2000) showed that women's marital problems spill over to other determinants of psychosocial health, such as anxiety, depression, perceived control, social relations, and self-esteem. A similar profile is true for men when experiencing stress at work. Wamala (2001), in a study of Swedish cohabiting working women, found that a stressful and abusive marriage contributed to a higher risk of developing a heart attack and a poorer prognosis. However, for women with a higher occupational status or high autonomy at work, marital conflicts did not seem to increase their risk for CHD.

Variations in the perception of quality of marital relations provide an empirical example of gender

differences in physiological reactions. Women demonstrate more detailed and vivid memories of marital relations (particularly negative experiences), and spend more time thinking about them than their husbands. Thus, women's stronger memories may contribute to their increased arousal to physiological responses as compared to men.

Experimental laboratory studies that measure physiological responses related to recall of stress from various situations are useful in understanding these gender differences. In the studies done by Brown and Smith (1992) and Brown, Smith, and Benjamin (1998), women, unlike men, showed more pathological physiological responses that predict a heart attack, when recalling stressors related to marital arguments, whereas similar responses were true for men when asked to recall stressors related with achievement challenge. Furthermore, Glaser, Kiecolt-Glaser, Malarkey, and Sheridan (1998), in their experimental study of physiological reactions to a marital conflict recall task, showed that marital conflicts increased levels of catecholamines,<sup>8</sup> corticotropin, and growth hormone in women but not in men. In another extended experiment by Carels, Sherwood, Szczepanski, and Blumenthal (2000), a recall of marital conflict, work conflict, and serial subtraction tasks was examined in married working women. The authors reported that elevated blood pressure was observed only when recalling stress evoked by a marital conflict. Carels et al., in their investigation of married employed women ages 25 to 45, further demonstrated that women with higher levels of marital distress exhibited greater negative emotions and higher levels of blood pressure that were more pronounced at home than at work.

Another interesting finding is that by Frankenhaeuser et al. (1989), based on middle managers at the Volvo automobile company in Sweden. A diurnal peak in urinary norepinephrine<sup>9</sup> excretion rates occurred in both men and women at about midday. Interestingly, men had decreased excretion soon after leaving the workplace, whereas women had an additionally higher peak of the catecholamines after arriving home from work.

This section emphasizes that there are more than "biological" explanations to the different physiological responses in men and women. Autonomy and control, particularly at work, seem to buffer the negative effects from the family sphere, which may influence health in a different way for men and women.

## CONCLUDING REMARKS

Macroeconomic forces, culture, and traditions create and contribute to how gender roles, distribution of power, and access to resources are patterned in society. The burden on women due to multiple roles of wage earner, parent, and caregiver is a public health concern. Both men's and women's physiology are negatively influenced by adverse working conditions. However, women's health is more often influenced by unfavorable family situations, which may be buffered by a more favorable work environment.

Gender is a dynamic concept and varies with time, generation, and changes in society. Gender differences in health can be better understood by evaluating how gender interacts with socioeconomic position and ethnicity.

Gender inequity is an important public health issue. Public health interventions should address parenting responsibilities, distribution of power and economic resources, autonomy, equal opportunities, and equal rights for men and women.

—Sarah P. Wamala and Gunnar Agren

## Notes

1. Vertical segregation occurs when some jobs are male dominated and others are female dominated.
2. Horizontal segregation refers to an unequal distribution of power and influence for men and women within the same occupational classes.
3. Emotional support refers to close emotional ties and an emotional atmosphere in which individuals can express their feelings freely and without self-consciousness.
4. Belongingness refers to the feeling of belonging to a larger group, where experiences, information, and ideas can be shared because of similar situations or similar objectives.
5. Tangible support refers to the provision of tangible goods (e.g., food, money) or task-oriented services (e.g., transportation, cooking).
6. Appraisal support refers to the communication of advice or appraisal of a situation and information relevant to self-evaluation and decision making.
7. Metabolic syndrome involves high levels of triglycerides, low levels of high-density lipoprotein (HDL; the "good" cholesterol), high blood pressure, and glucose intolerance.
8. The major catecholamines are dopamine, norepinephrine, and epinephrine. Epinephrine is a neurotransmitter in the brain but is also a major hormone in the body.

9. Norepinephrine is the primary neurotransmitter in the sympathetic nervous system and is also in the brain.

## GENERAL ADAPTATION SYNDROME

---

Modern ideas regarding stress and its effects on the body date from the classic work of physiologist Walter Cannon (1929). Cannon studied the physiological processes involved in the maintenance of homeostasis and observed what he called the *fight-or-flight* response. The fight-or-flight response involves a chain of biochemical reactions that begin with the stimulation of the cerebral cortex once the threat has been perceived. Among other responses, the cerebral cortex triggers the hypothalamus, which activates the sympathetic nervous system, which, in turn, stimulates the adrenal cortex to secrete cortisol and the adrenal medulla to secrete the hormones epinephrine and norepinephrine (catecholamines). The circulation of these hormones triggers the physiological processes associated with the fight-or-flight response, including increases in heart rate, respiration, blood pressure, blood volume, blood sugar, and blood flow to the muscles and brain, and inhibition of major bodily systems such as digestion and reproduction.

Together, these physiological changes act to increase oxygen to the brain and muscles to mobilize the system for action. These processes can provide a temporary means of survival for the organism; however, they may have undesirable physiological consequences in the event of prolonged activation.

### THE WORK OF HANS SELYE

Hans Selye (1956) was the first to advance the notion of *stress* as a stimulus that elicits physiological responses to threat. Selye exposed laboratory rats to a variety of stimuli including toxins, insulin injections, electric shocks, and extreme temperatures. Extending Cannon's observation of catecholamines release, he noted that regardless of the stimulus, prolonged exposure activated the secretion of adrenocorticotrophic hormone (ACTH), which, in turn, stimulated the secretion of corticosteroids. In the short term, corticosteroids

serve to protect the body from harm by increasing energy levels through increases in blood sugar levels, reductions in immune response and inflammation of body tissue, and enhancement of muscle tone in the heart and blood vessels. However, prolonged secretion of these hormones may have the effect of increasing susceptibility to illness via increases in blood pressure, suppression of immune function, damage to muscle tissue, and weakening of the body's ability to fight infection. The observation of these nonspecific physiological processes in response to a broad range of stimuli led Selye to the formulation of the general adaptation syndrome (GAS). Thus, the physiological responses triggered by different stressful stimuli may be mediated through a common set of pathways.

### THE THREE PHASES OF THE GENERAL ADAPTATION SYNDROME

Selye hypothesized that these responses occur in three progressive phases (Figure 1). The first phase, *Alarm*, is triggered by a threatening encounter, during which the organism experiences the physiological responses involving the concurrent release of cortisol, norepinephrine, and epinephrine described by Cannon. Selye also noted that when an organism is confronted with stress, the hypothalamus activates another endocrine pathway, secondary to that noted by Cannon, in which corticosteroids are secreted from the adrenal medulla. Once the threat is eliminated, the acute physiological arousal of the Alarm phase diminishes.

During the second phase, *Resistance*, the organism's physiological systems prepare to return to normal homeostatic levels. If successful, the body will no longer show physical signs of stress. Most of the time the resistance phase is only successful in reversing the fight-or-flight response if the stressor is removed. However, if the threat continues, the organism enters a temporary state sustained by increased hormonal output that enables the organism to respond to the continuing demands of the threatening situation. While this stage is necessary for survival, the organism also incurs a physiological cost as physiological arousal remains elevated, and resistance to new stressors is weakened. If this state continues, it will eventually use up all of the energy and resources that were created to deal with the stressor, which initiates the final phase, *Exhaustion*. During the Exhaustion phase, the adaptive response to stress may be irreversibly

**Figure 1** The Three Phases of the General Adaptation Syndrome

impaired due to the depletion of physiological reserves. The body experiences adrenal exhaustion leading to decreased stress tolerance, progressive mental and physical exhaustion, illness, and collapse.

In accordance with Selye's observations, it has become apparent that cortisol release due to prolonged stress can be detrimental to several physiological systems. For example, stress can lead to high blood pressure and weight gain, two risk factors associated with cardiovascular disease and insulin resistance. Psychological disorders such as depression have also been linked to the overactivation of endocrine functioning through the continued release and depletion of norepinephrine. While the stress response to threat in the Alarm phase appears to be nonspecific, recovery from the Exhaustion phase is largely determined by the nature of the threat, its duration, and the method of coping employed by the organism. Adaptive coping responses such as stress management, relaxation, utilization of social support, and problem solving have been shown to significantly moderate the deleterious effects of prolonged stress on the organism's body systems, enabling faster recovery of stress resistance.

### ADDING AN EVALUATIVE COMPONENT: LAZARUS'S COGNITIVE-TRANSACTIONAL MODEL

The notion of coping arose from Richard Lazarus's cognitive-transactional model of stress, which defined stress as a "relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (Lazarus & Folkman, 1984, p. 19).

This definition added a psychological component to Selye's model, which was primarily developed to explain the effects of physical stressors. This new evaluative component would help explain why the sound of footsteps in a deserted alley would evoke a different response if one knows the source of the footsteps as a friend or a menacing stranger.

## CONCLUSIONS

The study of stress remains a central theme in health psychology, and its treatment remains a central concern of behavioral medicine. Yet, theorists continue to debate the precise meaning of the term *stress*, and controversy continues to exist concerning how it is measured, and the means by which it may be implicated in different pathophysiological states. The general adaptation syndrome was a useful organizing principle in that it provided a theoretical framework for understanding why a broad array of physical and psychological stimuli may act on common physiological pathways, and how stress may be implicated in chronic disease.

## GENETIC TESTING: ETHICAL, LEGAL, AND SOCIAL ASPECTS

Genetic advances raise questions of enormous importance to individuals and societies. Genes define our individual identity, while simultaneously linking us to family, ethnic group, and species. Genetic testing results that identify inherited predisposition for disease can define a state between illness and wellness. In some cases, identification as the carrier of a disease-predisposing mutation has implications for prognosis and for targeted prevention, early diagnosis, and possibly even treatment recommendations. In other cases, information about mutation status may have few immediate ramifications beyond the psychological impact of the knowledge itself.

Utilization of the end products of genetic research is dependent on what people understand about genetic testing, on social and individual attitudes toward genetics, and on the emotional state and life experiences of the potential users. The ultimate success of recent genetic advances including the cloning of the human genome is dependent on an informed public's awareness of the potential benefits and the risks of increased genetic knowledge. Success is further aided by the availability of appropriate genetic counseling and psychological services. These services can provide needed information, optimize decision making, improve individualized consideration of potential emotional and interpersonal consequences of genetic testing, and offer support to individuals and families coping with the burden and challenge of genetic knowledge.

## GENETIC TESTING

Genetic testing is a process whereby an individual's DNA, derived from a blood sample, is sequenced to determine if there are mutations or changes from the usual sequence that may indicate an inherited predisposition to disease. Genetic testing is not available for all hereditary diseases. Conditions such as sickle cell disease or phenylketonuria (PKU), which are the result of genetic mutations, can be identified by physical changes in the body that are

present at birth, so genetic testing is unnecessary. For many other hereditary conditions, however, it is impossible to identify carriers of disease predispositions prior to the onset of the illness, which often occurs in adulthood. With increasing genetic knowledge, tests have been developed for some hereditary conditions so that those who are tested can learn whether or not they carry disease-predisposing mutations.

To date, genetic testing has been available largely for Huntington's disease and for some cancer genes. Huntington's disease and hereditary breast, ovarian, and colon cancers are each caused by mutations in a single gene. The inherited predispositions that result from these mutations are guided by the principles of Mendelian genetics and are inherited in autosomal dominant patterns. This means that children of mothers or fathers who are mutation carriers have a 50-50 chance of inheriting the deleterious mutation. Whether or not the disease actually develops varies with the penetrance of the gene, which is the extent to which those who have the genetic mutation (the genotype) exhibit the disease or other characteristic (the phenotype). Penetrance varies with the population being considered. Most cancer genes, however, typically convey risks that are many times the risk of individuals in the general population. For example, the lifetime risk of breast cancer in women who are BRCA1/2 carriers ranges from 56% to 85%, compared to the risk for a woman in the general population, which is 1 in 8 or 1 in 9 (11-12%). Inherited mutations are thought to account for about 5% to 10% of all cancers.

In the future, we will understand more about other complex patterns that govern the inheritance of predisposition to both physical and psychiatric diseases. These patterns sometimes involve combinations of genes that must *all* be altered to trigger disease onset. Some hereditary disease predispositions also involve interactions between genes and environmental factors. This increasing complexity of genetic information challenges psychologists and genetics professionals to improve methods of information delivery to patients and health professionals. Since the basis of all ethical research and treatment is a reasonable understanding by those involved of the issues at hand, finding methods to improve and customize patient, public, family, and professional understanding of genetics is a critical aspect of the social integration of the new genetics.

### When Should Testing Be Made Available?

There are many concerns about when it is ethical to offer genetic testing. Important issues include whether testing should be available as soon as it becomes possible or whether it should be offered only when there are treatments or prevention strategies for the condition that the genetic mutation causes. Other questions concern the standards that should be established for genetic tests and how they should be upheld, and whether children should be tested for adult-onset disorders. Further ethical issues relate to whether one company should hold a patent for the test of a particular gene, effectively forcing all competitors from the market, and whether genetic testing should be marketed directly to members of the public.

There is a gap in public understanding about the steps that are necessary between the discovery of a gene in a laboratory setting and the reality of clinical genetic testing for the condition. Some blame this gap on the intense media attention that surrounds the discovery of a disease gene. They fault reporters' tendencies to leap ahead to describing the ultimate utility of the work without adequate caution about the scientific and medical problems that must be resolved before such goals can be realized.

This problem is confounded by the fact that, to find the disease gene, scientists must often get genetic samples from patients with the condition and their relatives. These individuals have a vested interest in the outcomes of the studies, although typically they are not given results of their own research testing, even once the gene is identified. This is because laboratory testing and testing for clinical purposes are governed by different standards of accuracy. It is crucial that individuals participating in such research efforts understand that they will likely not benefit personally from the testing. They may become part of a registry or group whose members are informed about the availability of genetic testing as soon as clinical testing becomes possible, but they will likely also need genetic counseling prior to getting the test results, so that they fully understand the consequences of testing. They will probably also have to provide another blood sample to be tested in a clinically approved (CLIA) laboratory.

The first genetic test for a major disorder was for Huntington's disease (HD), a progressive neurological disorder for which neither preventive nor curative treatments are available. The 100% penetrance of the

HD gene means that all who carry the mutation will develop the disease during their lifetime. Contrary to expectations of high interest among healthy relatives of HD patients based on surveys done prior to identification of the HD gene, uptake of testing has been minimal. Only about 10% of at-risk members of HD families have requested testing. Those who are tested say they seek resolution of the uncertainty that colors their lives and information to better plan their futures. There is relief for those found not to be carriers, although many also feel something like “survivor guilt” for family members who are not as lucky. Most of those found to be carriers say they prefer to have knowledge of their mutation status, although some depression and rare adverse outcomes are also reported.

People at increased hereditary disease risk appear to find the prospect of knowing their genetic status more appealing when it is hypothetical; when testing becomes possible, anxiety about the impact of the knowledge appears to impede uptake. Pretest interest among at-risk individuals was also not predictive of uptake of genetic testing for the BRCA1/2, the first two genes for hereditary breast and ovarian cancer. About a third to a half of at-risk individuals in selected samples of breast-ovarian cancer families have requested testing.

The patent for the BRCA1/2 mutations is held by Myriad Genetics, Inc., a private company that participated in the search for the genes and won the patent rights. Hence, all commercial BRCA1/2 testing has to be done by Myriad. Currently, there is some concern in the genetics world because Myriad is marketing the genetic test for BRCA1/2 directly to consumers. Many feel this is inappropriate, since it pressures individuals to be tested without adequate counseling about the limitations and alternatives to genetic testing and with insufficient preparation for possible adverse outcomes of having knowledge of one's genetic status.

### Who Should Have Access to Genetic Testing?

There is concern that many of the people to date who have sought and received genetic testing have been well-educated, Caucasian individuals from upper socioeconomic stratas. This is a function of many factors, but there are efforts under way to increase the availability of testing to minorities and cultural subgroups of the population. This is a complex

issue as it involves not merely translation of consent forms into non-English languages but more challenging issues of defining subpopulations; discovering and addressing stereotypes about research, in general, and genetics, more specifically; ensuring access to prevention and screening programs; and determining who the most trusted leaders are of any community whose aid may be needed to help introduce genetic testing to that community.

Another issue concerning cultural subgroups is the fact that some groups have been found to carry particularly high rates of disease-predisposing mutations. Within the Ashkenazi Jewish population, about 90% of mutations in BRCA1/2 are accounted for by two mutations in BRCA1 and one in BRCA2. This is due to what is called a *founder effect*, the increased presence in a population of a particular genetic mutation due to many centuries of restricted breeding within the group. Founder effects have also been observed in subpopulations of many other ethnic or cultural groups, but often not to the degree represented in the Ashkenazi Jewish population. This means that people who are Ashkenazi Jewish who do not know whether there is a BRCA1/2 mutation in their family and who do not have a living relative with breast or ovarian cancer who could be tested can still themselves be tested to see if they carry one of these three mutations. Testing for three mutations is about one tenth the cost of sequencing the entire gene. A positive test result would inform individuals that they are at increased risk of breast and ovarian cancer. A negative test, however, is not informative, since it is possible that, in their family, it is a different mutation that is responsible for increased rates of breast or ovarian cancer or it is possible that there is no inherited predisposition. This kind of negative result, then, is said to be “uninformative.”

The reaction to offering this kind of “panel” testing to Ashkenazi Jewish populations has varied widely. Some groups and their leaders have welcomed testing, feeling that having additional knowledge about disease risk is empowering. Other groups and leaders have been skeptical about the idea of isolating any subpopulation as carrying deleterious genes. They fear that this could have adverse social consequences, including discrimination. The issues raised by the availability of specialized testing within genetic subpopulations and the fact that future genetic research on genetic variation is likely to reveal unexpected differences and similarities within established social,

ethnic, and religious groups suggests a need for increased attention to the interface between culture, society, and medicine.

There are also questions about whether children should have genetic testing for conditions that do not occur until adulthood, such as breast and ovarian cancer or HD. The consensus has been that genetic testing for these conditions should be deferred so that persons can decide for themselves when they become adults whether they want to know their personal genetic risk. This attitude is supported by the finding that so many at-risk adults have opted against testing for themselves.

Sometimes, it is difficult for parents who are mutation carriers to accept that they must live for many years with uncertainty about whether their children carry the same mutation. If preventive interventions are developed that are usefully initiated in childhood, it is very likely that attitudes toward the testing of children for these conditions will change. It is currently the case that children at risk for familial adenomatous polyposis (FAP), an inherited form of colon cancer, are offered genetic testing, since preventive interventions for children in families in which FAP has occurred in adults are typically initiated around the age of 10. Genetic testing allows for the identification of the 50% of children in the family who do not carry mutations in the gene responsible for FAP, the APC gene. The children found not to be carriers do not need to undergo the repeated colonoscopies that are used to determine, often by age 16 or so, if and when part or all of an at-risk child's colon should be removed to prevent the occurrence of colon cancer. There is some research on the effects of genetic testing for APC mutations on children in FAP families that suggests that although most children do not have depression or anxiety reactions in the clinical range, some patients do have increased distress and, in one study, a tenth of the children said they regretted knowing their genetic risk status.

### **What Is the Impact of Learning That One Is at Increased Hereditary Risk for Disease?**

Research on the psychosocial impact of genetic testing indicates a mixed picture. Learning that one is a carrier of a predisposition gene, such as BRCA1/2 or the gene for HD, for serious physical and neurological conditions does not typically occasion immediate, severe adverse effects, as had been feared at the

beginning of the genetic testing era. Most people react with disappointment and some short-term distress. However, it appears that there is a subset of individuals for whom receiving news of their positive test result triggers depression, increased anxiety, and/or diminished self-esteem.

The interaction between baseline levels of distress, personality style, medical history, test result, and medical and psychosocial outcomes will be a topic of intense interest in the coming decade. This will be especially true as testing occurs with greater frequency outside of the research programs from which most current outcome data emanate. (Those programs offered extensive genetic counseling and often, free testing; these factors might well have influenced patients' satisfaction with the testing experience.) The distinction between "monitors," those who actively seek personal medical information, and "blunters," those who prefer to avoid thinking about such matters, is often invoked in distinguishing between those who believe that knowing their genetic status will empower them and those who find such knowledge unnecessarily distressing. Further study will spur development of counseling techniques targeted to the cognitive style and personality of the patient.

The ultimate goal of identifying those at increased hereditary risk for disease is to reduce morbidity and mortality and to diminish human suffering related to disease. Anxiety is a moderator of the relationship between knowledge and action. Some level of worry about developing the illness in question is necessary for an individual to take preventive action or to regularly undergo screening to detect the disease at the earliest possible point. When the level of risk is low, it is likely that undergoing screening will result in positive reassurance that the disease or its precursors are not present. However, if genetic testing indicates that an individual has a vastly increased disease risk, his or her anxiety about becoming ill is likely to increase, possibly interfering with getting recommended screenings or undertaking preventive measures. In such a case, the fruits of the genomic revolution are not realized. Rather, knowledge of genetic risk might actually increase the chances that the disease will not be discovered until it is so advanced that the most effective treatments are useless. This represents a challenge that must be addressed if the increasing knowledge about hereditary aspects of illness is to serve its intended purpose of reducing the burden of disease on those families and individuals with hereditary predispositions.

### What Are the Social Risks of Learning One's Personal Genetic Risk Status?

There has been much less reported insurance and other discrimination based on genetic test results than originally feared. Some contend that this means that the envisioned use of genetic test results by insurers to discriminate against mutation carriers has been overblown, often with the unintended effect of scaring at-risk individuals away from seeking genetic services. Others say it would be unwise to abandon efforts to protect genetic privacy now. They contend that the rarity of genetic discrimination is only because insurers are just now figuring out ways to get and evaluate genetic test data and to recalculate individual risk using genetic information. Many states and the federal government are working on legislation to protect genetic information, but there is no way that laws can fully protect people who want their genetic information to remain completely private. A Web site maintained by the Health Privacy Project at Georgetown University summarizes relevant state regulations and includes the definitions of terms used in the state laws (<http://www.healthprivacy.org>).

There are also questions about what the obligations of others are to protect those who do not want to learn their own genetic status from the information. Some ethicists have argued that there is a "right not to know," just as there is a right (at least of adults) to have information about their genetic makeup, if it is possible to know it and if they are willing to pay for and undergo testing. These questions, as well as issues about whether there is a duty to continually update patients and family members about changes in our knowledge about the mutations they carry, will create fertile arenas for psychological studies of attitudes and of the impact of different interpretations of "fairness" in the genetics context. Such data will be of great interest to those charged with making genetics policy.

### PSYCHIATRIC GENETICS

Genetics will have marked impact not only on our understanding of medical conditions but also on the definition and treatment of psychiatric disorders. Identification of the genetic basis for conditions such as Prader-Willi syndrome (PWS), the definition of which had previously relied solely on behavioral factors, allows for greater clarity in defining the

syndrome and diagnosing affected individuals. PWS is a genetic disorder characterized by a complex and variable symptom configuration including behavioral, cognitive, and physical abnormalities. Possible symptoms include lifelong hypotonia, insatiable appetite, short stature, and obsessive-compulsive behaviors, among others. Knowledge of the underlying genetic cause for the syndrome also provides new direction to the search for treatment and cure of PWS.

For many other psychiatric conditions, the genetic basis may be considerably more complicated. Nonetheless, as the interactions between genes or between genes and environmental factors are worked out, our knowledge and understanding of many psychiatric conditions and behavioral states are likely to greatly improve. It will be important that at-risk individuals and family members receive counseling about the implications of knowing whether or not there is a clear hereditary factor responsible for the illness in the family. Knowledge of a genetic etiology for childhood psychiatric disorders may remove some stigma from parents as the "cause" of their child's illness. However, stigma may attach instead to the child being a carrier of a mutation-conveying genetic predisposition to a mental disorder or disease.

### FAMILY COMMUNICATION

The presence of an inherited disease predisposition affects family life and communication between relatives in many ways. In turn, the nature of the communication between family members affects the manner in which genetic information is disseminated within the family and the medical and psychological outcomes of genetic testing.

Genetic counseling and testing necessitate the gathering of accurate information about family history, specifically, knowledge of which relatives had which diseases at what ages. To determine if there is a likely hereditary process involved, it is also often necessary to have quite specific information about the diagnosed illnesses and related conditions. These details often lead to intimate conversations between relatives who may not otherwise know each other particularly well. They may also uncover difficult and sometimes new information about the nature and course of a relative's illness, which may prove quite upsetting to some family members. Women are the prime carriers of familial information about illness. When the hereditary disease also primarily affects

women (such as in hereditary breast and ovarian cancer families), the premature death of many women may complicate access to accurate information about family medical history.

Genetic testing usually only gives definitive results when a family member with cancer (or other disease of hereditary etiology) is tested first. This may lead to the possibility of some relatives being pressured or even coerced to be tested, who would not themselves have sought testing. Difficult ethical conflicts may arise between one individual's desire for testing and that individual's dependence on the willingness of another, reluctant relative's decision about whether or not to undergo testing altruistically for the benefit of others in the family. Whose autonomy counts most? This issue, while resolved harmoniously in many families, can, in others, create deeply felt resentments. Psychological consultation can be useful in resolving such controversies.

## FUTURE GENETIC INTERVENTIONS

Pharmacogenetics promises medicines targeted to the particular, inherited characteristics of the person for whom it is prescribed. The hope is that by understanding the genetics that govern the way a particular drug is ingested and absorbed by different people, special forms of the medication can be produced for those different groups of consumers, thereby reducing side effects, toxicity, and underdosing. Testing for those genes that determine drug response may become quite common, bringing with it ethical concerns about who possesses and stores knowledge of gene status related to drug sensitivities.

Gene therapy is an ultimate goal of much of the new genetics. The hope is that by enlarging our understanding of gene function, we will be better able not only to identify carriers of disease-predisposing genetic mutations but also to treat the resulting conditions or to prevent disease development. However, use of gene therapy raises ethical and psychological issues related to determination of which conditions merit remediation and when treatment leads down a slippery slope of seeking endlessly for human perfection. Questions arise about who will have access to this expensive therapy and whether our approach to individuals with disabilities will be changed by the possibility of genetically "fixing" many hereditary conditions. Issues of patient and family understanding and informed consent become more salient as new,

complicated, genetic treatments are developed that may have many unforeseen side effects.

Advances in genetics brought about by the Human Genome Project will change many aspects of medical care in coming decades and will likely alter our conceptions of race, gender, and the health-illness continuum. Mental health professionals in clinical settings will see increasing numbers of patients with concerns about the identification of risk for inherited disease predisposition and related family issues. Psychologists and other social scientists contribute to our understanding of the impact of genetic advances on individuals, families, and society. Research on the acceptance, uptake, and outcomes of genetic testing, much of it sponsored by the Ethical, Legal, and Social Implications (ELSI) program of the National Institute of Human Genome Research, is helping to answer questions about the ways in which people understand genetic information and when and how that information can be utilized to reduce human distress. Research on social and psychological outcomes of genetic testing is advanced by the 5% of the Human Genome budget devoted to the study of ethical, legal, and social implications. The ELSI program represents a remarkable advance in medically related social science research in its insistence on concurrent study of the social issues and problems resulting from advancing scientific knowledge. Its goals include minimizing adverse effects and improving access for all social groups to new genetic information and the resulting tests and treatments.

To keep abreast of changing genetic knowledge requires continuing education. Web sites maintained by the National Human Genome Research Institute (<http://www.genome.gov/>), the National Cancer Institute ([www.cancernet.org](http://www.cancernet.org)), and others are valuable resources. The National Coalition for Health Professional Education in Genetics (NCHPEG) ([www.nchpeg.org](http://www.nchpeg.org)) is also developing resources to broaden the genetic understanding of health professionals.

# Appendix A

## Online Resources and Health and Behavior Organizations

Agency for Healthcare Research and Quality  
2101 E. Jefferson Street, Suite 501  
Rockville, MD 20852  
Telephone: 301-594-1364  
<http://www.ahrpr.gov/>

According to its Web site, the “mission of the Agency for Health Care Policy and Research is to support, conduct, and disseminate research that improves access to care and the outcomes, quality, cost, and utilization of health care services. The research sponsored and conducted by the Agency provides better information that enables better decisions about health care” (in 1999, the Agency for Health Care Policy and Research changed its name to the Agency for Healthcare Research and Quality, AHRQ).

Alan Guttmacher Institute  
120 Wall Street, 21st Floor  
New York, NY 10005  
Telephone: 212-248-1111  
[www.agi-usa.org/](http://www.agi-usa.org/)

The Alan Guttmacher Institute is a nonprofit organization focused on sexual and reproductive health research, policy analysis, and public education. The institute’s mission is to protect the reproductive choices of all women and men in the United States and throughout the world. It is to support their ability to obtain the information and services needed to achieve their full human rights, safeguard their health, and exercise their individual responsibilities in regard to sexual behavior and relationships, reproduction, and family formation.

Alzheimer’s Association  
225 North Michigan Avenue, Suite 1700  
Chicago, IL 60601-7633  
Telephone: 312-335-8700  
<http://www.alz.org/>

The Alzheimer’s Association, a national network of chapters, is the largest national voluntary health organization dedicated to advancing Alzheimer’s research and helping those affected by the disease. Having awarded \$136 million in research grants, the association ranks as the top private funder of research into the causes, treatments, and prevention of Alzheimer’s disease. The association also provides education and support for people diagnosed with the condition, their families, and caregivers.

American Academy of Child and Adolescent Psychiatry  
3615 Wisconsin Avenue N.W.  
Washington, DC 20016-3007  
Telephone: 202-966-7300  
<http://www.aacap.org>

The American Academy of Child and Adolescent Psychiatry (AACAP) is a membership-based organization, composed of more than 6,500 child and adolescent psychiatrists and other interested physicians. Its members actively research, evaluate, diagnose, and treat psychiatric disorders and pride themselves on giving direction to and responding quickly to new developments in addressing the health care needs of children and their families.

American Academy of Nursing  
600 Maryland Avenue, S.W., Suite 100 West  
Washington, DC 20024-2571  
Telephone: 202-651-7238  
[www.nursingworld.org/aan/](http://www.nursingworld.org/aan/)

The American Academy of Nursing is constituted to potentiate the contributions of nursing leaders in transforming the health care system to optimize public well-being. This leadership is grounded in a global perspective, enriched by diversity, and actualized through partnerships with other health care and consumer groups.

American Academy of Pediatrics  
141 Northwest Point Boulevard  
Elk Grove Village, IL 60007-1098  
Telephone: 847-434-4000  
<http://www.aap.org/>

The American Academy of Pediatrics (AAP) and its member pediatricians dedicate their efforts and resources to the health, safety, and well-being of all infants, children, adolescents, and young adults. The AAP has 57,000 members in the United States, Canada, and Latin America. Members include pediatricians, pediatric medical subspecialists, and pediatric surgical specialists. More than 41,000 members are board certified and are called Fellows of the American Academy of Pediatrics (FAAP).

American Association of Colleges of Nursing  
One Dupont Circle, N.W., Suite 530  
Washington, DC 20036  
Telephone: 202-463-6930  
<http://www.aacn.nche.edu/>

The American Association of Colleges of Nursing (AACN) is the national voice for America's baccalaureate- and higher-degree nursing education programs. AACN's educational, research, government advocacy, data collection, publications, and other programs work to establish quality standards for bachelor's- and graduate-degree nursing education, assist deans and directors to implement those standards, influence the nursing profession to improve health care, and promote public support of baccalaureate and graduate education, research, and practice in nursing.

American Association of Spinal Cord Injury Psychologists  
and Social Workers  
75-20 Astoria Boulevard.  
Jackson Heights, NY 11370

Telephone: 718-803-3782  
<http://www.aascipsw.org/>

The American Association of Spinal Cord Injury Psychologists and Social Workers (AASCIPSW) is an organization of psychologists and social workers who provide for the emotional, behavioral, and psychosocial care of persons affected by spinal cord impairment (SCI). AASCIPSW, incorporated in 1986, operates exclusively for scientific, charitable, and educational purposes. AASCIPSW provides members the opportunity to develop and refine leadership skills through active participation in the association.

American Association of Suicidology  
4201 Connecticut Avenue, N.W., Suite 408  
Washington, DC 20008  
Telephone: 202-237-2280  
[www.suicidology.org/](http://www.suicidology.org/)

The goal of the American Association of Suicidology (AAS) is to understand and prevent suicide. AAS promotes research, public awareness programs, public education, and training for professionals and volunteers. In addition, AAS serves as a national clearinghouse for information on suicide. The membership of AAS includes mental health and public health professionals, researchers, suicide prevention and crisis intervention centers, school districts, crisis center volunteers, survivors of suicide, and a variety of laypersons who have an interest in suicide prevention.

American Cancer Society  
<http://www.cancer.org>  
Telephone: 1-800-ACS-2345

The American Cancer Society (ACS) is a nationwide, community-based voluntary health organization. With chartered divisions throughout the country and more than 3,400 local offices, the ACS is committed to fighting cancer through balanced programs of research, education, patient service, advocacy, and rehabilitation.

American College of Preventive Medicine  
1307 New York Avenue, N.W., Suite 200  
Washington, DC 20005  
Telephone: 202-466-2044  
[www.acpm.org](http://www.acpm.org)

The American College of Preventive Medicine (ACPM) is the national professional society for physicians committed to disease prevention and health promotion.

American Counseling Association  
5999 Stevenson Avenue  
Alexandria, VA 22304  
Telephone: 1-800-347-6647  
[www.counseling.org](http://www.counseling.org)

The American Counseling Association (ACA) is a not-for-profit, professional and educational organization dedicated to the growth and enhancement of the counseling profession. Founded in 1952, ACA is the world's largest association exclusively representing professional counselors in various practice settings. ACA has been instrumental in setting professional and ethical standards for the counseling profession.

American Diabetes Association  
National Center  
1701 North Beauregard Street  
Alexandria, VA 22311  
Telephone: 1-800-DIABETES (1-800-342-2383)  
[www.diabetes.org](http://www.diabetes.org)

The American Diabetes Association is the nation's leading nonprofit health organization providing diabetes research, information, and advocacy. The mission of the organization is to prevent and cure diabetes and to improve the lives of all people affected by diabetes.

American Heart Association  
National Center  
7272 Greenville Avenue  
Dallas, TX 75231  
Telephone: 1-800-AHA-USA-1 or 1-800-242-8721  
[www.americanheart.org](http://www.americanheart.org)

The American Heart Association is a national voluntary health agency whose mission is to reduce disability and death from cardiovascular diseases and stroke.

American Institute of Stress  
124 Park Avenue  
Yonkers, NY 10703  
Telephone: 914-963-1200  
<http://www.stress.org/>

The American Institute of Stress is committed to developing a better understanding of how to tap into the vast innate potential that resides in each of us for preventing disease and promoting health.

American Psychiatric Association  
1000 Wilson Boulevard, Suite 1825

Arlington, VA 22209-3901  
Telephone: 703-907-7300  
[www.psych.org](http://www.psych.org)

The American Psychiatric Association is a medical specialty society recognized worldwide. Its 37,000 U.S. and international member physicians work together to ensure humane care and effective treatment for all persons with mental disorders, including mental retardation and substance-related disorders. It is the voice and conscience of modern psychiatry. Its vision is a society that has available accessible quality psychiatric diagnosis and treatment.

American Psychological Association  
750 First Street, N.E.  
Washington, DC 20002-4242  
Telephone: 1-800-374-2721 or 202-336-5500  
[www.apa.org](http://www.apa.org)

The American Psychological Association (APA) is a scientific and professional organization that represents psychology in the United States. With more than 155,000 members, APA is the largest association of psychologists worldwide. APA's initiatives include supporting psychology as a science, profession, and means to improve health and human welfare; educating the public and the media on the value of psychology; advocating in legislatures, educational settings, and major social institutions on behalf of the discipline and psychologists; and working to advance education and training in psychology from preschool to postdoctorate levels.

American Psychological Society  
1010 Vermont Avenue N.W., Suite 1100  
Washington, DC 20005-4907  
Telephone: 202-783-2077  
<http://www.psychologicalscience.org/>

The mission of the American Psychological Society (APS) is to promote, protect, and advance the interests of scientifically oriented psychology in research, application, teaching, and the improvement of human welfare. The APS is a nonprofit membership organization founded in 1988 to advance scientific psychology and its representation as a science on the national level. APS grew quickly, surpassing 5,000 members in its first 6 months. In 2003, APS membership exceeded 13,500 and includes the leading psychological scientists and academics, clinicians, researchers, teachers, and administrators.

American Psychosocial Oncology Society  
2365 Hunters Way  
Charlottesville, VA 22911  
Telephone: 434-293-5350  
[www.apos-society.org/](http://www.apos-society.org/)

The mission of American Psychosocial Oncology Society is to promote the psychological, social, and physical well-being of patients with cancer and their families at all stages of disease and survivorship through clinical care, education, research, and advocacy.

American Psychosomatic Society  
6728 Old McLean Village Drive  
McLean, VA 22101-3906  
Telephone: 703-556-9222  
[www.psychosomatic.org](http://www.psychosomatic.org)

The mission of the American Psychosomatic Society is to promote and advance the scientific understanding of the interrelationships among biological, psychological, social, and behavioral factors in human health and disease, and the integration of the fields of science that separately examine each, and to foster the application of this understanding in education and improved health care.

American Public Health Association  
800 I Street, N.W.  
Washington, DC 20001  
Telephone: 202-777-2742  
<http://www.apha.org/>

The American Public Health Association (APHA) is the oldest and largest organization of public health professionals in the world, representing more than 50,000 members from over 50 occupations of public health. APHA brings together researchers, health service providers, administrators, teachers, and other health workers in a unique, multidisciplinary environment of professional exchange, study, and action. APHA is concerned with a broad set of issues affecting personal and environmental health, including federal and state funding for health programs, pollution control, programs and policies related to chronic and infectious diseases, a smoke-free society, and professional education in public health.

American Social Health Association  
P.O. Box 13827  
Research Triangle Park, NC 27709  
Telephone: 919-361-8400  
<http://www.ashastd.org/>

The American Social Health Association is recognized by the public, patients, providers, and policymakers for developing and delivering accurate, medically reliable information about sexually transmitted diseases.

American Society for Clinical Nutrition  
9650 Rockville Pike  
Bethesda, MD 20814-3998  
Telephone: 301-530-7110  
[www.faseb.org/ascn/](http://www.faseb.org/ascn/)

The American Society for Clinical Nutrition (ASCN) is the clinical division of the American Society for Nutritional Sciences. The goals and objectives of the ASCN are to encourage and implement undergraduate and graduate education in basic and clinical nutrition, particularly in medical schools; expand research and clinical training opportunities in nutrition science for health professionals; and provide opportunities for investigators to present and discuss current research in human nutrition.

American Society for Nutritional Sciences  
9650 Rockville Pike, Suite 4500  
Bethesda, MD 20814  
Telephone: 301-530-7050  
[www.asns.org/](http://www.asns.org/)

The American Society for Nutritional Sciences is the premier research society dedicated to improving the quality of life through the science of nutrition.

American Sociological Association  
1307 New York Avenue, N.W., Suite 700  
Washington, DC 20005  
Telephone: 202-383-9005  
<http://www.asanet.org/>

The American Sociological Association (ASA) is a membership association dedicated to advancing sociology as a scientific discipline and profession serving the public good. With approximately 13,000 members, ASA encompasses sociologists who are faculty members at colleges and universities, researchers, practitioners, and students.

Association for Applied Psychophysiology and Biofeedback  
10200 W. 44th Avenue, Suite 304  
Wheat Ridge, CO 80033-2840, USA  
Telephone: 303-422-8436  
[www.aapb.org](http://www.aapb.org)

The mission of the Association for Applied Psychophysiology and Biofeedback (AAPB) is to advance the development, dissemination, and utilization of knowledge about applied psychophysiology and biofeedback to improve health and the quality of life through research, education, and practice. The goals of the association are to promote a new understanding of biofeedback and advance the methods used in this practice.

Association for the Advancement of Behavior Therapy  
305 7th Avenue, 16th Floor  
New York, NY 10001  
Telephone: 212-647-1890  
[www.aabt.org](http://www.aabt.org)

The Association for the Advancement of Behavior Therapy (AABT) is a professional, interdisciplinary organization that is concerned with the application of behavioral and cognitive sciences to the understanding of human behavior, developing interventions to enhance the human condition, and promoting the appropriate utilization of these interventions. AABT is a not-for-profit membership organization of more than 4,500 mental health professionals and students who are interested in behavior therapy and cognitive behavior therapy in order to gain a better understanding of human behavior; develop, assess, and apply interventions to assist in behavior change; help people deal with personal and social problems and issues; and further the empirical study, theory, and practice of these therapies.

Association of Behavior Analysis  
1219 South Park Street  
Kalamazoo, MI 49001  
Telephone: 269-492-9310  
<http://www.abainternational.org/>

The mission of the Association of Behavior Analysis is to develop, enhance, and support the growth and vitality of behavioral analysis through research, education, and practice.

Association of State and Territorial Directors of  
Health Promotion and Public Health Education  
1101 15th Street, N.W., Suite 601  
Washington, DC 20005  
Telephone: 202-659-2230  
[www.astdhphe.org](http://www.astdhphe.org)

The Association of State and Territorial Directors of Health Promotion and Public Health Education

(ASTDHPHE) was founded in 1946 (as the Conference of State Directors of Public Health Education) as a joint effort between directors of health education in state health departments and deans of health education in schools of public health. In 1994, the association changed its name to the Association of State and Territorial Directors of Health Promotion and Public Health Education to better reflect the mission and roles of the membership in promoting health and preventing disease in states and communities.

Association of Teachers of Preventive Medicine  
1660 L Street, N.W., Suite 208  
Washington, DC 20036  
Telephone: 202-463-0550  
<http://www.atpm.org/>

The Association of Teachers of Preventive Medicine (ATPM) is the national association supporting health promotion and disease prevention educators and researchers. Since 1942, ATPM and its members have been in the forefront of advancing, promoting, and supporting health promotion and disease prevention in the education of physicians and other health professionals.

Behavior OnLine  
[www.behavior.net/about.html](http://www.behavior.net/about.html)

Behavior OnLine aspires to be the premier World Wide Web gathering place for mental health professionals and applied behavioral scientists—a place where professionals of every discipline can feel at home.

Center for Behavioral Neuroscience  
[www.cbn-atl.org](http://www.cbn-atl.org)

The Center for Behavioral Neuroscience examines the neural mechanisms underlying the social behaviors that are essential for species survival, such as fear, affiliation, aggression, and reproductive behaviors.

Center for Communication Programs  
Johns Hopkins Bloomberg School of Public Health  
111 Market Place, Suite 310  
Baltimore, MD 21202  
Telephone: 410-659-6300  
[www.jhuccp.org/](http://www.jhuccp.org/)

The Center for Communication Programs (CCP) works with international agencies, foundations, governments, and nongovernmental organizations in the United States and overseas to promote healthy behavior.

The CCP's work focuses on the field of strategic, research-based communication for behavior change and health promotion that has helped transform the theory and practice of public health.

Center for the Advancement of Health  
2000 Florida Avenue, N.W., Suite 210  
Washington, DC 20009-1231  
Telephone: 202-387-2829  
[www.cfah.org/](http://www.cfah.org/)

The Center for the Advancement of Health promotes a view of health that recognizes that where we live, how we are educated, and what we eat, drink, breathe, and do affect health as much as, if not more than, access to health care. Its mission is to translate research on this expanded view of health into effective policy and practice.

Centers for Disease Control and Prevention  
1600 Clifton Road  
Atlanta, GA 30333  
Telephone: 404-639-3311  
[www.cdc.gov](http://www.cdc.gov)

The Centers for Disease Control and Prevention (CDC) is recognized as the lead federal agency for protecting the health and safety of people, at home and abroad, providing credible information to enhance health decisions and promoting health through strong partnerships. The CDC serves as the national focus for developing and applying disease prevention and control, environmental health, and health promotion and education activities designed to improve the health of the people of the United States. The CDC's mission is to promote health and quality of life by preventing and controlling disease, injury, and disability.

College on Problems of Drug Dependence  
3420 N. Broad Street  
Philadelphia, PA 19140  
Telephone: 215-707-3242  
<http://www.cpdd.vcu.edu/>

The College on Problems of Drug Dependence (CPDD), formerly the Committee on Problems of Drug Dependence, has been in existence since 1929 and is the longest-standing group in the United States addressing problems of drug dependence and abuse. CPDD serves as an interface among government, industrial, and academic communities maintaining liaisons with regulatory and research agencies as well

as educational, treatment, and prevention facilities in the drug abuse field. It also functions as a collaborating center of the World Health Organization.

Commission on Accreditation of Rehabilitation Facilities  
4891 E. Grant Road  
Tucson, AZ 85712  
Telephone: 520-325-1044  
[www.carf.org](http://www.carf.org)

The Commission on Accreditation of Rehabilitation Facilities (CARF) is an independent, not-for-profit accrediting body promoting quality, value, and optimal outcomes of services through a consultative accreditation process that centers on enhancing the lives of the persons receiving services. Founded in 1966 as the Commission on Accreditation of Rehabilitation Facilities, the accrediting body is now known as CARF. The mission of CARF is to promote the quality, value, and optimal outcomes of services through a consultative accreditation process that centers on enhancing the lives of the persons served.

Consortium of Social Science Associations  
1522 K Street, N.W., Suite 836  
Washington, DC 20005  
Telephone: 202-842-3525  
<http://www.cossa.org/>

The Consortium of Social Science Associations (COSSA) is an advocacy organization supported by more than 100 professional associations, scientific societies, universities, and research institutions. COSSA stands alone in representing the full range of social scientists. COSSA represents the needs and interests of social and behavioral scientists; educates federal officials about social and behavioral science; informs the science community about relevant federal policies; and cooperates with other science and education groups in pursuit of common goals. COSSA lobbies Congress and the Executive Branch on issues affecting the social science portfolios of the National Science Foundation, the National Institutes of Health, the Departments of Agriculture, Commerce, Education, Justice, and Labor, and many other federal agencies.

Council of Graduate Departments of Psychology  
<http://psych.wfu.edu/cogdop/>

The Council of Graduate Departments of Psychology (COGDOP) is a society constituted of chairs and heads of departments of psychology or other equivalent administrative units, which are authorized to offer

graduate degrees in psychology in institutions accredited by their regional accrediting association. Membership is held by the department, not by the individual.

Decade of Behavior  
750 First Street, N.E.  
Washington, DC 20002-4242  
Telephone: 202-336-6166  
[www.decadeofbehavior.org](http://www.decadeofbehavior.org)

The Decade of Behavior, launched in September 2000, is a multidisciplinary initiative to focus the talents, energy, and creativity of the behavioral and social sciences on meeting many of society's most significant challenges. These include improving education and health care; enhancing safety in homes and communities; actively addressing the needs of an aging population; and helping to curb drug abuse, crime, high-risk behaviors, poverty, racism, and cynicism toward government.

Federation of Behavioral, Psychological and Cognitive Sciences  
750 First Street, N.E.  
Washington, DC 20002  
Telephone: 202-336-5920  
<http://www.thefederationonline.org/>

The Federation of Behavioral, Psychological and Cognitive Sciences is a dues-supported coalition of member organizations, university departments of psychology, schools of education, research centers, regional psychological associations, and science divisions of the American Psychological Association. The federation represents the interests of scientists who do research in the areas of behavioral, psychological, and cognitive sciences. The efforts of the federation are focused on legislative and regulatory advocacy, education, and the communication of information to scientists.

Gerontological Society of America  
1030 15th Street, N.W., Suite 250  
Washington, DC 20005  
Telephone: 202-842-1275  
<http://www.geron.org/>

The Gerontological Society of America (GSA) is a nonprofit professional organization with more than 5,000 members in the field of aging. GSA provides researchers, educators, practitioners, and policymakers with opportunities to understand, advance, integrate, and use basic and applied research on aging to improve the quality of life as one ages.

Healthfinder  
P.O. Box 1133  
Washington, DC 20013-1133  
[www.healthfinder.gov/](http://www.healthfinder.gov/)

Healthfinder is a guide to reliable health information from the Department of Health and Human Services. The guide includes a health library of hand-picked health information from A to Z—prevention and wellness, diseases and conditions, and alternative medicine—plus medical dictionaries, an encyclopedia, journals, and more.

Health Psychology, Division 38 of the American Psychological Association  
750 First Street, N.E.  
Washington, DC 20002-4242  
Telephone: 202-336-6013  
[www.apa.org/about/division/div38.html](http://www.apa.org/about/division/div38.html)

Division 38 seeks to advance contributions of psychology to the understanding of health and illness through basic and clinical research, education, and service activities and encourages the integration of biomedical information about health and illness with current psychological knowledge. The division has a nursing and health group and special interest groups in aging, women, and minority health issues. The division publishes the bimonthly journal *Health Psychology* and the quarterly newsletter *Health Psychologist*. Division 38 offers a listing of training programs in health psychology and presents an annual student paper award.

Human Factors and Ergonomics Society  
P.O. Box 1369  
Santa Monica, CA 90406-1369  
Telephone: 310-394-2410  
<http://www.hfes.org/>

The mission of the Human Factors and Ergonomics Society is to promote the discovery and exchange of knowledge concerning the characteristics of human beings that are applicable to the design of systems and devices of all kinds. The society was founded in 1957 as the Human Factors Society of America. Later, the name was changed to the Human Factors Society, Inc., to reflect its international influence and membership. In 1992, the name was changed to the Human Factors and Ergonomics Society.

Institute for the Advancement of Human Behavior  
4370 Alpine Road, Suite 209

Portola Valley, CA 94028  
Telephone: 1-800-258-8411  
[www.iahb.org](http://www.iahb.org)

The Institute for the Advancement of Human Behavior (IAHB) is a fully accredited sponsor of continuing education and continuing medical education for mental health, chemical dependency, and substance abuse treatment providers in the United States and Canada. IAHB's mission is to provide high-quality clinical training to health care professionals as well as to companies and individuals with health care-related interests.

Institute for the Advancement of Social Work Research  
750 First Street, N.E., Suite 700  
Washington, DC 20002-4241  
Telephone: 202-336-8385  
<http://www.iaswresearch.org/>

The Institute for the Advancement of Social Work Research (IASWR) is a Washington, D.C.-based non-profit organization. IASWR works to improve the lives of vulnerable populations by advocating for the importance of research to strengthen the social work profession's capacity to address complex social needs, and to contribute to improved prevention and treatment interventions, services, and policies. The overarching, single mission of IASWR is to promote and strengthen research in the social work profession.

Institute of Medicine  
The National Academies  
500 Fifth Street, N.W.  
Washington, DC 20001  
Telephone: 202-334-2138  
[www.iom.edu/](http://www.iom.edu/)

The mission of the Institute of Medicine (IOM) is to advance and disseminate scientific knowledge to improve human health. The institute provides objective, timely, authoritative information and advice concerning health and science policy to government, the corporate sector, the professions, and the public. IOM is part of the National Academy of Sciences organizations and does not receive direct federal appropriations for its work. The National Academy of Sciences was created by the federal government to be an adviser on scientific and technological matters.

Intercultural Cancer Council  
6655 Travis, Suite 322  
Houston, TX 77030-1312

Telephone: 713-798-4617  
<http://iccnetwork.org>

The Intercultural Cancer Council (ICC) promotes policies, programs, partnerships, and research to eliminate the unequal burden of cancer among racial and ethnic minorities and medically underserved populations in the United States and its associated territories.

International Psycho-Oncology Society  
2365 Hunters Way  
Charlottesville, VA 22911  
Telephone: 434-971-4788  
<http://www.ipos-society.org>

The International Psycho-Oncology Society (IPOS) was created to foster international multidisciplinary communication about clinical, educational, and research issues that relate to the subspecialty of psycho-oncology. The society seeks to provide leadership and development of standards for educational training and research in the two psychosocial dimensions of cancer: the response of patients, families, and staff to cancer and its treatment at all stages, and the psychological, social, and behavioral factors that influence tumor progression and survival. It has boundaries with all clinical oncologic specialties, epidemiology and cancer control, basic sciences, bioethics, palliative care, rehabilitation, clinical trials, and decision making.

International Social Science Council  
UNESCO House  
1, rue Miollis  
75732 Paris Cedex 15, France  
<http://www.unesco.org/ngo/issc/sommaire.htm>

The International Social Science Council (ISSC) is an international nonprofit scientific organization with its headquarters in UNESCO House in Paris. The ISSC has as its aims and objectives the promotion of the understanding of human society in its environment by fostering the social and behavioral sciences throughout the world and their application to major contemporary problems and by enhancing cooperation by means of a global international organization of social and behavioral scientists and social and behavioral science organizations, encouraging multidisciplinary and interdisciplinary cooperation among the members of the ISSC.

International Society for Developmental Psychobiology  
<http://www.oswego.edu/isdp/>

The purposes of the International Society for Developmental Psychobiology are to (a) promote and encourage research on the development of behavior in all organisms including humans, with special attention to the effects of biological factors operating at any level of organization; (b) facilitate communication of research results and theory in the area of developmental psychobiology through the use of both professional and popular printed media and through the presentation of papers at meetings of the society; and (c) foster application of the valid findings of research to human affairs in a way beneficial to humankind.

International Society of Behavioral Medicine  
[www.isbm.miami.edu](http://www.isbm.miami.edu)

The International Society of Behavioral Medicine (ISBM) is a federation of national societies whose goal is to serve the needs of all health-related disciplines concerned with issues relevant to behavioral medicine. Each national society includes both biomedical and behavioral scientists.

MEDLINEplus  
<http://medlineplus.gov/>

MEDLINEplus is a Web site with authoritative consumer health information from the National Institutes of Health and others.

MEDLINE/PubMed  
[www.ncbi.nih.gov/entrez/query.fcgi](http://www.ncbi.nih.gov/entrez/query.fcgi)

MEDLINE/PubMed is a database with references, primarily from MEDLINE, to journal articles in life sciences with a concentration on articles in the biomedical field.

The Metanexus Institute  
3624 Market Street, Suite 301  
Philadelphia, PA 19104  
Telephone: 215-789-2200  
[www.metanexus.net](http://www.metanexus.net)

The Metanexus Institute advances research, education, and outreach on the constructive engagement of science and religion. It seeks to create an enduring intellectual and social movement by collaborating with persons and communities from diverse religious traditions and scientific disciplines.

National Academy of Neuropsychology  
2121 South Oneida Street, Suite 550  
Denver, CO 80224-2594

Telephone: 303-691-3694  
<http://www.nanonline.org/>

The National Academy of Neuropsychology is a professional society that includes clinicians, scientist practitioners, and researchers interested in neuropsychology.

National Academy of Sciences  
500 Fifth Street, N.W.  
Washington, DC 20001  
Telephone: 202-334-2000  
<http://www4.nationalacademies.org/nas/nashome.nsf>

The National Academy of Sciences (NAS) is a private, nonprofit, self-perpetuating society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare. The academy is governed by a council composed of 12 members (councilors) and five officers, elected from among the academy membership. The council is responsible to the membership for the activities undertaken by the organization and for the corporate management of the National Academy of Sciences, a corporation created by act of Congress that also includes the National Academy of Engineering (NAE), the Institute of Medicine (IOM), and the National Research Council (NRC). Collectively, these organizations are called the National Academies.

National Cancer Institute  
6116 Executive Boulevard, MSC 8322  
Bethesda, MD 20892-8322  
Telephone: 1-800-422-6237  
[www.nci.nih.gov/](http://www.nci.nih.gov/)

The National Cancer Institute (NCI) leads a national effort to reduce the burden of cancer morbidity and mortality. Its goal is to stimulate and support scientific discovery and its application to achieve a future when all cancers are uncommon and easily treated. Through basic and clinical biomedical research and training, NCI conducts and supports programs to understand the causes of cancer; prevent, detect, diagnose, treat, and control cancer; and disseminate information to the practitioner, patient, and public.

National Center for Complementary and Alternative Medicine  
Bethesda, MD 20892  
Telephone: 1-888-644-6226  
[www.nccam.nih.gov/](http://www.nccam.nih.gov/)

The National Center for Complementary and Alternative Medicine (NCCAM) is dedicated to exploring complementary and alternative medical (CAM) practices in the context of rigorous science, training CAM researchers, and disseminating authoritative information.

National Center for Research Resources  
One Democracy Plaza, Room 984  
6701 Democracy Boulevard, MSC 4874  
Bethesda, MD 20892-4874  
Telephone: 301-435-0888  
[www.ncrr.nih.gov/](http://www.ncrr.nih.gov/)

The National Center for Research Resources (NCRR) advances biomedical research and improves human health through research projects and shared resources that create, develop, and provide a comprehensive range of human, animal, technological, and other resources. NCRR's support is concentrated in four areas: biomedical technology, clinical research, comparative medicine, and research infrastructure.

National Center on Minority Health and Health Disparities  
6707 Democracy Boulevard, Suite 800, MSC 5465  
Bethesda, MD 20892-5465  
Telephone: 301-402-1366  
[www.ncmhd.nih.gov/](http://www.ncmhd.nih.gov/)

The mission of the National Center on Minority Health and Health Disparities (NCMHD) is to promote minority health and to lead, coordinate, support, and assess the National Institutes of Health effort to reduce and ultimately eliminate health disparities. In this effort, NCMHD will conduct and support basic, clinical, social, and behavioral research; promote research infrastructure and training; foster emerging programs; disseminate information; and reach out to minority and other health disparity communities.

National Heart, Lung, and Blood Institute  
Bethesda, MD 20892  
Telephone: 301-592-8573  
[www.nhlbi.nih.gov/](http://www.nhlbi.nih.gov/)

The National Heart, Lung, and Blood Institute (NHLBI) provides leadership for a national program in diseases of the heart, blood vessels, lung, and blood; blood resources; and sleep disorders. NHLBI plans, conducts, fosters, and supports an integrated and coordinated program of basic research, clinical investigations and trials, observational studies, and demonstration and education projects.

National Human Genome Research Institute  
[www.nhgri.nih.gov/](http://www.nhgri.nih.gov/)

The National Human Genome Research Institute (NHGRI) supports the National Institutes of Health component of the Human Genome Project, a worldwide research effort designed to analyze the structure of human DNA and determine the location of the estimated 30,000 to 40,000 human genes.

National League for Nursing  
61 Broadway  
New York, NY 10006  
Telephone: 1-800-669-1656 or 212-363-5555  
<http://www.nln.org/>

The National League for Nursing advances quality nursing education that prepares the nursing workforce to meet the needs of diverse populations in an ever-changing health care environment.

National Institute of Allergy and Infectious Diseases  
Building 31, Room 7A-50, MSC 2520  
31 Center Drive  
Bethesda, MD 20892-2520  
[www.niaid.nih.gov/](http://www.niaid.nih.gov/)

National Institute of Allergy and Infectious Diseases (NIAID) research strives to understand, treat, and ultimately prevent the myriad infectious, immunologic, and allergic diseases that threaten millions of human lives.

National Institute of Arthritis and  
Musculoskeletal and Skin Diseases  
1 AMS Circle  
Bethesda, MD 20892-3675  
Telephone: 301-495-4484  
[www.niams.nih.gov/](http://www.niams.nih.gov/)

The National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) supports research into the causes, treatment, and prevention of arthritis and musculoskeletal and skin diseases, the training of basic and clinical scientists to carry out this research, and the dissemination of information on research progress in these diseases.

National Institute of Child Health and Human  
Development  
Building 31, Room 2A32, MSC 2425  
31 Center Drive  
Bethesda, MD 20892-2425  
[www.nichd.nih.gov/](http://www.nichd.nih.gov/)

National Institute of Child Health and Human Development (NICHD) research on fertility, pregnancy, growth, development, and medical rehabilitation strives to ensure that every child is born healthy and wanted and grows up free from disease and disability.

National Institute of Dental and Craniofacial Research  
Bethesda, MD 20892-2190  
Telephone: 301-496-4261  
[www.nidcr.nih.gov/](http://www.nidcr.nih.gov/)

The National Institute of Dental and Craniofacial Research (NIDCR) provides leadership for a national research program designed to understand, treat, and ultimately prevent the infectious and inherited craniofacial-oral-dental diseases and disorders that compromise millions of human lives.

National Institute of Diabetes and Digestive and Kidney Diseases  
Building 31, Room 9A04, MSC 2560  
Center Drive  
Bethesda, MD 20892  
[www.niddk.nih.gov/](http://www.niddk.nih.gov/)

The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) conducts and supports basic and applied research and provides leadership for a national program in diabetes, endocrinology, and metabolic diseases; digestive diseases and nutrition; and kidney, urologic, and hematologic diseases. Several of these diseases are among the leading causes of disability and death; all seriously affect the quality of life of those who have them.

National Institutes of Health  
9000 Rockville Pike  
Bethesda, MD 20892  
[www.nih.gov/](http://www.nih.gov/)

The National Institutes of Health (NIH) is the steward of medical and behavioral research for the United States. Its mission is science in pursuit of fundamental knowledge about the nature and behavior of living systems and the application of that knowledge to extend healthy life and reduce the burdens of illness and disability. The goals of the agency are as follows: (1) foster fundamental creative discoveries, innovative research strategies, and their applications as a basis to advance significantly the nation's capacity to protect and improve health; (2) develop, maintain, and renew scientific human and physical resources that will assure the nation's capability to prevent disease;

(3) expand the knowledge base in medical and associated sciences in order to enhance the nation's economic well-being and ensure a continued high return on the public investment in research; and (4) exemplify and promote the highest level of scientific integrity, public accountability, and social responsibility in the conduct of science.

National Institute of Mental Health  
6001 Executive Boulevard, Room 8184, MSC 9663  
Bethesda, MD 20892  
Telephone: 301-443-4513  
[www.nimh.nih.gov/](http://www.nimh.nih.gov/)

The National Institute of Mental Health (NIMH) provides national leadership dedicated to understanding, treating, and preventing mental illnesses through basic research on the brain and behavior, and through clinical, epidemiological, and services research.

National Institute of Neurological Disorders and Stroke  
P.O. Box 5801  
Bethesda, MD 20824  
Telephone: 1-800-352-9424  
[www.ninds.nih.gov/](http://www.ninds.nih.gov/)

The mission of the National Institute of Neurological Disorders and Stroke (NINDS) is to reduce the burden of neurological diseases—a burden borne by every age group, every segment of society, and people all over the world. To accomplish this goal, the NINDS supports and conducts research, both basic and clinical, on the normal and diseased nervous system, fosters the training of investigators in the basic and clinical neurosciences, and seeks better understanding, diagnosis, treatment, and prevention of neurological disorders.

National Institute of Nursing Research  
[www.ninr.nih.gov/](http://www.ninr.nih.gov/)

The National Institute of Nursing Research (NINR) supports clinical and basic research to establish a scientific basis for the care of individuals across the life span—from the management of patients during illness and recovery to the reduction of risks for disease and disability; the promotion of healthy lifestyles; the promotion of quality of life in those with chronic illness; and the care for individuals at the end of life. This research may also include families within a community context, and it also focuses on the special needs of at-risk and underserved populations, with an emphasis on health disparities.

National Institute on Aging  
Building 31, Room 5C27, MSC 2292  
31 Center Drive  
Bethesda, MD 20892  
Telephone: 301-496-1752  
[www.nia.nih.gov/](http://www.nia.nih.gov/)

The National Institute on Aging (NIA) leads a national program of research on the biomedical, social, and behavioral aspects of the aging process; the prevention of age-related diseases and disabilities; and the promotion of a better quality of life for all older Americans.

National Institute on Alcohol Abuse and Alcoholism  
6000 Executive Boulevard, Willco Building  
Bethesda, MD 20892-7003  
[www.niaaa.nih.gov/](http://www.niaaa.nih.gov/)

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) conducts research focused on improving the treatment and prevention of alcoholism and alcohol-related problems to reduce the enormous health, social, and economic consequences of this disease.

National Institute on Deafness and  
Other Communication Disorders  
MSC 2320  
31 Center Drive  
Bethesda, MD 20892-2320  
[www.nidcd.nih.gov/](http://www.nidcd.nih.gov/)

The National Institute on Deafness and Other Communication Disorders (NIDCD) conducts and supports biomedical research and research training on normal mechanisms as well as diseases and disorders of hearing, balance, smell, taste, voice, speech, and language that affect 46 million Americans.

National Institute on Drug Abuse  
[www.nida.nih.gov/](http://www.nida.nih.gov/)

The National Institute on Drug Abuse (NIDA) leads the nation in bringing the power of science to bear on drug abuse and addiction through support and conduct of research across a broad range of disciplines and rapid and effective dissemination of results of that research to improve drug abuse and addiction prevention, treatment, and policy.

National Library of Medicine  
8600 Rockville Pike  
Bethesda, MD 20894  
[www.nlm.nih.gov/](http://www.nlm.nih.gov/)

The National Library of Medicine (NLM) collects, organizes, and makes available biomedical science information to investigators, educators, and practitioners and carries out programs designed to strengthen medical library services in the United States. Both health professionals and the public use its electronic databases, including MEDLINE and MEDLINEplus, extensively throughout the world.

National Science Foundation  
4201 Wilson Boulevard  
Arlington, VA 22230  
Telephone: 703-292-5111  
[www.nsf.gov](http://www.nsf.gov)

The National Science Foundation (NSF) is an independent agency of the U.S. government. The NSF's mission is to promote the progress of science; to advance the national health, prosperity, and welfare; and to secure the national defense.

Neurobehavioral Teratology Society  
<http://www.nbts.org/>

The purpose of the Neurobehavioral Teratology Society (NBTS) is to understand the behavioral and developmental alterations that result from genetic and environmental perturbations of the nervous system during the pre- and perinatal period. NBTS is also focused on communicating such findings to physicians, scientists, public health officials, and the general public to promote awareness and lessen the risks for teratologic occurrences in the population at large. NBTS also has a special focus of educating scientists in the appropriate methodology for conducting teratologic research.

Office of Behavioral and Social Sciences Research  
<http://obssr.od.nih.gov/>

The Office of Behavioral and Social Sciences Research (OBSSR) mission is to stimulate behavioral and social sciences research throughout the National Institutes of Health (NIH) and to integrate these areas of research more fully into others of the NIH health research enterprise, thereby improving our understanding, treatment, and prevention of disease.

Office of Disease Prevention and Health Promotion  
200 Independence Avenue S.W., Room 738G  
Washington, DC 20201  
Telephone: 202-205-8611  
[www.odphp.osophs.dhhs.gov/](http://www.odphp.osophs.dhhs.gov/)

Created by Congress in 1976, the Office of Disease Prevention and Health Promotion (ODPHP) plays a vital role in developing and coordinating a wide range of national disease prevention and health promotion strategies.

Psychology.info  
<http://psychology.info/>

Psychology.info is the easiest starting point for psychology and mental health information on the Internet. The links are handpicked psychology destinations with reliable information and include recent headlines in the field of psychology.

PsychoNeuroImmunology Research Society  
6619 Palma Lane  
Morton Grove, IL 60053  
[www.pnirs.org](http://www.pnirs.org)

The PsychoNeuroImmunology Research Society (PNIRS) is an international organization for researchers in a number of scientific and medical disciplines, including psychology, neurosciences, immunology, pharmacology, psychiatry, behavioral medicine, infectious diseases, and rheumatology, who are interested in interactions between the nervous system and the immune system, and the relationship between behavior and health.

Psychonomic Society  
1710 Fortview Road  
Austin, TX 78704  
Telephone: 512-462-2442  
<http://www.psychonomic.org/>

The Psychonomic Society promotes the communication of scientific research in psychology and allied sciences. Its members are qualified to conduct and supervise scientific research, must hold a PhD degree or equivalent, and must have published significant research other than the doctoral dissertation.

Psych web  
[www.psywww.com/](http://www.psywww.com/)

Psych web is a Web site containing lots of psychology-related information for students and teachers of psychology.

Public Health Institute  
2001 Addison Street, Second Floor  
Berkeley, CA 94704-1103  
Telephone: 510-644-8200  
<http://www.phi.org/>

The Public Health Institute (PHI) is an independent, nonprofit organization dedicated to promoting health, well-being, and quality of life for people throughout California, across the nation, and around the world. As one of the largest and most comprehensive public health organizations in the nation, the PHI focuses its efforts in two distinct but complementary ways. PHI promotes and sustains independent, innovative research, training, and demonstration programs—many in collaboration with the private health care system and community-based organizations. PHI also serves as a partner with government to support its role in assessment, policy development, and assurance.

Research Society on Alcoholism  
4314 Medical Parkway, Suite 12  
Austin, TX 78756-3332  
Telephone: 512-454-0022  
<http://www.rsoa.org/>

The Research Society on Alcoholism (RSA) serves as a meeting ground for scientists in the broad areas of alcoholism and alcohol-related problems. The society promotes research and the acquisition and dissemination of scientific knowledge.

Robert Wood Johnson Foundation  
P.O. Box 2316  
Princeton, NJ 08543  
Telephone: 1-888-631-9989  
[www.rwjf.org](http://www.rwjf.org)

The Robert Wood Johnson Foundation is the largest philanthropy devoted exclusively to health and health care in the United States. The Robert Wood Johnson Foundation seeks to improve the health and health care of all Americans. To achieve the most impact with its funds, it prioritizes grants into four goal areas: to ensure that all Americans have access to quality health care at reasonable cost; to improve the quality of care and support for people with chronic health conditions; to promote healthy communities and lifestyles; and to reduce the personal, social, and economic harm caused by substance abuse—tobacco, alcohol, and illicit drugs.

Science.gov  
[www.science.gov](http://www.science.gov)

Science.gov is a gateway to authoritative selected science information provided by U.S. government agencies, including research and development results. It contains reliable information resources selected by

the respective agencies as their best science information. Two major types of information are included—selected authoritative science Web sites and databases of technical reports, journal articles, conference proceedings, and other published materials. The selected Web sites can be explored from the science.gov homepage. The Web pages and the databases can be searched individually or simultaneously from the search page.

Social Sciences Institute  
North Carolina AT&T University  
Charles H. Moore Building, A-35  
Greensboro, NC 27411  
[www.ssi.nrcs.usda.gov/ssi/](http://www.ssi.nrcs.usda.gov/ssi/)

The Social Sciences Institute (SSI) integrates customer opinion and fieldwork with science-based analysis to discover how social and economic aspects of human behavior can be applied to natural resource conservation programs, policies, and activities.

Society of Behavioral Medicine  
7600 Terrace Avenue, Suite 203  
Middleton, WI 53562  
Telephone: 608-827-7267  
[www.sbm.org](http://www.sbm.org)

The Society of Behavioral Medicine (SBM) is the nation's largest multidisciplinary organization dedicated to advancing the science and practice of behavioral medicine. Behavioral medicine is defined as an interdisciplinary field dedicated to improving individual and population health through the integration of scientific knowledge from the behavioral, biomedical, social, and public health disciplines and through the application of this evidence-based knowledge to improve prevention, treatment, rehabilitation, chronic illness management, quality of life, and coping during all phases of the life cycle.

Society for Behavioral Neuroendocrinology  
4327 Ridge Road  
Palmyra, VA 22963  
[www.sbn.org](http://www.sbn.org)

The Society for Behavioral Neuroendocrinology (SBN) is a scientific society committed to understanding interactions between behavior and neuroendocrine function to advance understanding of behavioral neuroendocrinology. The society promotes exchanges between investigators approaching this problem from diverse perspectives. Researchers working in

laboratory, field, or clinical settings and on invertebrates, vertebrates, or cell lines both in vitro and in vivo are encouraged to join the society. Scientists interested in behavioral ecology, animal behavior, biological timing, neurosciences, endocrinology, development, cell biology, and genetics are all welcome. One's research need not explicitly employ behavioral techniques as long as the research is relevant to behavior. Similarly, behavioral research need not employ neuroendocrine techniques, but only be related to neuroendocrine function. Integrating cellular and molecular concepts into a functional framework is crucial to understanding how neuroendocrine function affects behavior and is, in turn, affected by behavior.

Society for Medical Decision Making  
1211 Locust Street  
Philadelphia, PA 19107  
Telephone: 215-545-7697  
<http://www.smdm.org/>

The Society for Medical Decision Making's mission is to improve health outcomes through the advancement of proactive systematic approaches to clinical decision making and policy formation in health care by providing a scholarly forum that connects and educates researchers, providers, policymakers, and the public.

Society for Neuroscience  
11 Dupont Circle, N.W., Suite 500  
Washington, DC 20036  
Telephone: 202-462-6688  
[www.sfn.org](http://www.sfn.org)

The Society for Neuroscience (SfN) is a nonprofit membership organization of basic scientists and physicians who study the brain and nervous system. Neuroscience includes the study of brain development, sensation and perception, learning and memory, movement, sleep, stress, aging, and neurological and psychiatric disorders. It also includes the molecules, cells, and genes responsible for nervous system functioning.

Society of Pediatric Psychology  
P.O. Box 170231  
Atlanta, GA 30317  
[www.apa.org/divisions/div54/](http://www.apa.org/divisions/div54/)

The Society of Pediatric Psychology (SPP) provides a forum for scientists and professionals interested in the health care of children, adolescents, and

their families. The field of pediatric psychology is defined by the concerns of psychologists and allied professionals who work in interdisciplinary settings such as children's hospitals, developmental clinics, and pediatric or medical group practices, as well as traditional clinical child or academic arenas. It focuses on the rapidly expanding role of behavioral medicine and health psychology in the care of children, adolescents, and their families. As Division 54 of the American Psychological Association (APA), it provides an annual forum for research and practice presentations at the annual APA convention.

Society for Prevention Research  
1300 I Street, N.W., Suite 250 West  
Washington, DC 20005  
Telephone: 202-216-9670  
<http://info@preventionresearch.org>

One of the primary goals of the Society for Prevention Research (SPR) is to create a scientific, multidisciplinary forum for prevention science, and a concerted effort is being made to invite investigators whose research specialties are not represented in the current membership to join SPR.

Society for Psychophysiological Research  
1010 Vermont Avenue, N.W., Suite 1100  
Washington, DC 20005-4907  
Telephone: 202-393-4810  
[www.wlu.edu/~spr/](http://www.wlu.edu/~spr/)

The Society for Psychophysiological Research is an international scientific society with worldwide membership. The purpose of the society is to foster research on the interrelationships between the physiological and psychological aspects of behavior.

Society for Public Health Education  
750 First Street N.E., Suite 910  
Washington, DC 20002-4242  
Telephone: 202-408-9804  
<http://www.sophe.org/>

The Society for Public Health Education (SOPHE) is an independent, international professional association made up of a diverse membership of health education professionals and students. The society promotes healthy behaviors, healthy communities, and healthy environments through its membership, its network of local chapters, and its numerous partnerships with other organizations. With its primary focus on public health education, SOPHE provides leadership

through a code of ethics; standards for professional preparation, research, and practice; professional development; and public outreach.

Society for Research in Child Development  
University of Michigan  
3131 South State Street, Suite 302  
Ann Arbor, MI 48108-1623  
<http://www.srcd.org/>

The purposes of the Society for Research in Child Development are to promote multidisciplinary research in the field of human development, to foster the exchange of information among scientists and other professionals of various disciplines, and to encourage applications of research findings. The society is a multidisciplinary, not-for-profit, professional association with a membership of approximately 5,500 researchers, practitioners, and human development professionals from more than 50 countries.

Society for Research on Nicotine and Tobacco  
7600 Terrace Avenue, Suite 203  
Middleton, WI 53562, USA  
Telephone: 608-836-3787  
[www.srnt.org/](http://www.srnt.org/)

The mission of the Society for Research on Nicotine and Tobacco (SRNT) is to stimulate the generation of new knowledge concerning nicotine in all its manifestations—from molecular to societal.

Society for Stimulus Properties of Drugs  
<http://www.sspd.org.uk/>

The Society for Stimulus Properties of Drugs (SSPD) supports the use of drug discrimination methods and some related approaches in teaching and research on psychoactive drugs. Many of these drugs have medical uses in psychiatry and neurology, whereas others have no recognized medical uses but may be under development for such use, or are subject to abuse. Both licit and illicit substances are included. Membership of SSPD is open to individuals with bachelor or higher degrees in relevant subjects and with a genuine interest in the field.

Substance Abuse and Mental Health Services Agency  
5600 Fishers Lane  
Rockville, MD 20857  
[www.samhsa.gov/](http://www.samhsa.gov/)

The Substance Abuse and Mental Health Services Agency (SAMHSA) is the federal agency charged with improving the quality and availability of prevention, treatment, and rehabilitative services in order to reduce illness, death, disability, and cost to society resulting from substance abuse and mental illnesses.

U.S. National Committee of the International Union of Psychological Science  
<http://www.iupsys.org/>

The International Union of Psychological Science serves as an umbrella international voice supporting “the development of psychological science, whether biological or social, normal or abnormal, pure or applied.” It has national members from close to 70 countries, and works to represent the full breadth of psychology as a profession and as a science.

Women’s Health Initiative  
[www.nhlbi.nih.gov/whi/](http://www.nhlbi.nih.gov/whi/)  
[www.whi.org/](http://www.whi.org/)

The Women’s Health Initiative (WHI) is one of the largest preventive studies of its kind in the United States. The WHI is a 15-year research program that is composed of three major components: a randomized controlled clinical trial of promising but unproven approaches to prevention, an observational study to identify predictors of disease, and a study of community approaches to developing healthful behaviors.

World Health Organization  
Avenue Appia 20  
1211 Geneva 27, Switzerland  
Telephone: (+ 41 22) 791 21 11  
<http://www.who.int>

The World Health Organization (WHO), the United Nations specialized agency for health, was established in 1948. WHO’s mission is the attainment by all peoples of the highest possible level of health. Health is defined in WHO’s constitution as a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.
